Preface to the Sixth Edition	xi
Acknowledgments	xiii
List of Symbols	xv
CHAPTER 1 Introduction: Basic Principles	1
1.1 Definition of a Turbomachine	1
1.2 Coordinate System	2
1.3 The Fundamental Laws	4
1.4 The Equation of Continuity	5
1.5 The First Law of Thermodynamics	5
1.6 The Momentum Equation	7
1.7 The Second Law of Thermodynamics—Entropy	9
1.8 Bernoulli's Equation	11
1.9 Compressible Flow Relations	12
1.10 Definitions of Efficiency	15
1.11 Small Stage or Polytropic Efficiency	18
1.12 The Inherent Unsteadiness of the Flow within Turbomachines	24
References	26
Problems	26
CHAPTER 2 Dimensional Analysis: Similitude	29
2.1 Dimensional Analysis and Performance Laws	29
2.2 Incompressible Fluid Analysis	30
2.3 Performance Characteristics for Low Speed Machines	32
2.4 Compressible Fluid Analysis	33
2.5 Performance Characteristics for High Speed Machines	37
2.6 Specific Speed and Specific Diameter	40
2.7 Cavitation	47
References	49
Problems	50
CHAPTER 3 Two-Dimensional Cascades	53
3.1 Introduction	53
3.2 Cascade Geometry	56
3.3 Cascade Flow Characteristics	59
3.4 Analysis of Cascade Forces	64
3.5 Compressor Cascade Performance	68

3.6	Turbine Cascades	78
	References	92
	Problems	94
CHAPTER 4	Axial-Flow Turbines: Mean-Line Analysis and Design	97
4.1	Introduction	97
4.2	Velocity Diagrams of the Axial-Turbine Stage	99
4.3	Turbine Stage Design Parameters	100
4.4	Thermodynamics of the Axial-Turbine Stage	101
4.5	Repeating Stage Turbines	103
4.6	Stage Losses and Efficiency	105
4.7	Preliminary Axial Turbine Design	107
4.8	Styles of Turbine	109
4.9	Effect of Reaction on Efficiency	113
4.10	Diffusion within Blade Rows	115
4.11	The Efficiency Correlation of Smith (1965)	118
4.12	Design Point Efficiency of a Turbine Stage	121
4.13	Stresses in Turbine Rotor Blades	125
4.14	Turbine Blade Cooling	131
4.15	Turbine Flow Characteristics	133
	References	136
	Problems	137
CHAPTER 5	Axial-Flow Compressors and Ducted Fans	143
5.1	Introduction	143
5.2	Mean-Line Analysis of the Compressor Stage	144
5.3	Velocity Diagrams of the Compressor Stage	146
5.4	Thermodynamics of the Compressor Stage	147
5.5	Stage Loss Relationships and Efficiency	148
5.6	Mean-Line Calculation Through a Compressor Rotor	149
5.7	Preliminary Compressor Stage Design	153
5.8	Simplified Off-Design Performance	157
5.9	Multi-Stage Compressor Performance	159
5.10	High Mach Number Compressor Stages	165
5.11	Stall and Surge Phenomena in Compressors	166
5.12	Low Speed Ducted Fans	172
5.13	Blade Element Theory	174
5.14	Blade Element Efficiency	176
5.15	Lift Coefficient of a Fan Aerofoil	176
	References	177
	Problems	179

CHAPTER 6	Three-Dimensional Flows in Axial Turbomachines	183
6.1	Introduction	183
6.2	Theory of Radial Equilibrium	183
6.3	The Indirect Problem	185
6.4	The Direct Problem	193
6.5	Compressible Flow Through a Fixed Blade Row	194
6.6	Constant Specific Mass Flow	195
6.7	Off-Design Performance of a Stage	197
6.8	Free-Vortex Turbine Stage	198
6.9	Actuator Disc Approach	200
6.10	Computer-Aided Methods of Solving the Through-Flow Problem	206
6.11	Application of Computational Fluid Dynamics to the Design of Axial Turbomachines	209
6.12	Secondary Flows	210
	References	212
	Problems	213
CHAPTER 7	Centrifugal Pumps, Fans, and Compressors	217
7.1	Introduction	217
7.2	Some Definitions	220
7.3	Thermodynamic Analysis of a Centrifugal Compressor	221
7.4	Diffuser Performance Parameters	225
7.5	Inlet Velocity Limitations at the Eye	229
7.6	Optimum Design of a Pump Inlet	230
7.7	Optimum Design of a Centrifugal Compressor Inlet	232
7.8	Slip Factor	236
7.9	Head Increase of a Centrifugal Pump	242
7.10	Performance of Centrifugal Compressors	244
7.11	The Diffuser System	251
7.12	Choking In a Compressor Stage	256
	References	258
	Problems	259
CHAPTER 8	Radial Flow Gas Turbines	265
8.1	Introduction	265
8.2	Types of Inward-Flow Radial Turbine	266
8.3	Thermodynamics of the 90° IFR Turbine	268
8.4	Basic Design of the Rotor	270
8.5	Nominal Design Point Efficiency	272
8.6	Mach Number Relations	276
8.7	Loss Coefficients in 90° IFR Turbines	276

8.8	Optimum Efficiency Considerations	278
8.9	Criterion for Minimum Number of Blades	283
8.10	Design Considerations for Rotor Exit	286
8.11	Significance and Application of Specific Speed	291
8.12	Optimum Design Selection of 90° IFR Turbines	294
8.13	Clearance and Windage Losses	296
8.14	Cooled 90° IFR Turbines	297
	References	298
	Problems	299
CHAPTER 9	Hydraulic Turbines	303
9.1	Introduction	303
9.2	Hydraulic Turbines	305
9.3	The Pelton Turbine	308
9.4	Reaction Turbines	317
9.5	The Francis Turbine	317
9.6	The Kaplan Turbine	324
9.7	Effect of Size on Turbomachine Efficiency	328
9.8	Cavitation	330
9.9	Application of CFD to the Design of Hydraulic Turbines	334
9.10	The Wells Turbine	334
9.11	Tidal Power	346
	References	349
	Problems	350
CHAPTER 10	Wind Turbines	357
10.1	Introduction	357
10.2	Types of Wind Turbine	360
10.3	Outline of the Theory	364
10.4	Actuator Disc Approach	364
10.5	Estimating the Power Output	372
10.6	Power Output Range	372
10.7	Blade Element Theory	373
10.8	The Blade Element Momentum Method	381
10.9	Rotor Configurations	389
10.10	The Power Output at Optimum Conditions	397
10.11	HAWT Blade Section Criteria	398
10.12	Developments in Blade Manufacture	399
10.13	Control Methods (Starting, Modulating, and Stopping)	400
10.14	Blade Tip Shapes	405
10.15	Performance Testing	406

10.16	Performance Prediction Codes	406
10.17	Environmental Considerations	408

Preface to the Sixth Edition

This book was originally conceived as a text for students in their final year reading for an honours degree in engineering that included turbomachinery as a main subject. It was also found to be a useful support for students embarking on post-graduate courses at masters level. The book was written for engineers rather than for mathematicians, although some knowledge of mathematics will prove most useful. Also, it is assumed from the start that readers will have completed preliminary courses in fluid mechanics. The stress is placed on the actual physics of the flows and the use of specialised mathematical methods is kept to a minimum.

Compared to the fifth edition this new edition has had a large number of changes made in style of presentation, new ideas and clarity of explanation. More emphasis is given to the effects of compressibility to match the advances made in the use of higher flow and blade speeds in turbomachinery. In Chapter 1, following the definition of a turbomachine, the fundamental laws of flow continuity, the energy and entropy equations are introduced as well as the all-important Euler work equation, which applies to all turbomachines. In Chapter 2 the main emphasis is given to the application of the “similarity laws,” to dimensional analysis of all types of turbomachine and their performance characteristics. The important ideas of specific speed and specific diameter emerge from these concepts and their application is illustrated in the Cordier Diagram, which shows how to select the machine that will give the highest efficiency for a given duty. Did you realise that the *dental drill* is actually a turbomachine that fits in very well with these laws? Also, in this chapter the basics of cavitation within pumps and hydraulic turbines are examined.

The measurement and understanding of cascade aerodynamics is the basis of modern axial turbomachine design and analysis. In Chapter 3, the subject of cascade aerodynamics is presented in preparation for the following chapters on axial turbines and compressors. This chapter has been completely reorganised relative to the fifth edition. It starts by presenting the parameters that define the blade section geometry and performance of any axial turbomachine. The particular considerations for axial compressor blades are then presented followed by those for axial turbine blades. The emphasis is on understanding the flow features that constrain the design of turbomachine blades and the basic prediction of cascade performance. Transonic flow can dramatically modify the characteristics of a blade row and special attention is given to the effects of compressibility on cascade aerodynamics.

Chapters 4 and 5 cover axial turbines and axial compressors, respectively. In Chapter 4, new material has been developed to cover the preliminary design and analysis of single- and multi-stage axial turbines. The calculations needed to fix the size, the number of stages, the number of aerofoils in each blade row, and the velocity triangles are covered. The merits of different styles of turbine design are considered including the implications for mechanical design such as centrifugal stress levels and cooling in high speed and high temperature turbines. Through the use of some relatively simple correlations the trends in turbine efficiency with the main turbine parameters are presented. In Chapter 5, the analysis and preliminary design of all types of axial compressors are covered. This includes a new presentation of how measurements of cascade loss and turning can be translated into the performance of a compressor stage. Both incompressible and compressible cases are covered in the chapter and it is interesting to see how high speed compressors can achieve a pressure rise through quite a different flow process to that in a low speed machine. The huge importance of off-design performance is

covered in some detail including how the designer can influence compressor operating range in the very early design stages. There is also a selection of new examples and problems involving the compressible flow analysis of high speed compressors.

Chapter 6 covers three-dimensional effects in axial turbomachinery. The aim of this chapter is to give the reader an understanding of spanwise flow variations and to present some of the main flow features that are not captured within mean-line analysis. It includes a brief introduction to the subject of computational fluid dynamics, which now plays a large part in turbomachinery design and analysis. Detailed coverage of computational methods is beyond the scope of this book. However, all the principles detailed in this book are equally applicable to numerical and experimental studies of turbomachines.

Radial turbomachinery remains hugely important for a vast number of applications, such as turbocharging for internal combustion engines, oil and gas transportation, and air liquefaction. As jet engine cores become more compact there is also the possibility of radial machines finding new uses within aerospace applications. The analysis and design principles for centrifugal compressors and radial inflow turbines are covered in Chapters 7 and 8. Improvements have been made relative to the fifth edition including new examples, corrections to the material, and reorganization of some sections.

Renewable energy topics were first added to the fourth edition of this book by way of the Wells turbine and a new chapter on hydraulic turbines. In the fifth edition a new chapter on wind turbines was added. Both of these chapters have been retained in this edition as the world remains increasingly concerned with the very major issues surrounding the use of various forms of energy. There is continuous pressure to obtain more power from renewable energy sources and hydroelectricity and wind power have a significant role to play. In this edition, hydraulic turbines are covered in Chapter 9, which includes coverage of the Wells turbine, a new section on tidal power generators, and several new example problems. Chapter 10 covers the essential fluid mechanics of wind turbines, together with numerous worked examples at various levels of difficulty. Important aspects concerning the criteria of blade selection and blade manufacture, control methods for regulating power output and rotor speed, and performance testing are touched upon. Also included are some very brief notes concerning public and environmental issues, which are becoming increasingly important as they, ultimately, can affect the development of wind turbines.

To develop the understanding of students as they progress through the book, the expounded theories are illustrated by a selection of worked examples. As well as these examples, each chapter contains problems for solution, some easy, some hard. See what you can make of them!

Acknowledgments

The authors are indebted to a large number of people in publishing, teaching, research, and manufacturing organisations for their help and support in the preparation of this volume. In particular thanks are given for the kind permission to use photographs and line diagrams appearing in this edition, as listed below:

ABB (Brown Boveri, Ltd)
American Wind Energy Association
Bergey Windpower Company
Elsevier Science
Hodder Education
Institution of Mechanical Engineers
Kvaener Energy, Norway
Marine Current Turbines Ltd., UK
National Aeronautics and Space Administration (NASA)
NREL
Rolls-Royce plc
The Royal Aeronautical Society and its Aeronautical Journal
Siemens (Steam Division)
Sirona Dental
Sulzer Hydro of Zurich
Sussex Steam Co., UK
U.S. Department of Energy
Voith Hydro Inc., Pennsylvania
The Whittle Laboratory, Cambridge, UK.

I would like to give my belated thanks to the late Professor W. J. Kearton of the University of Liverpool and his influential book *Steam Turbine Theory and Practice*, who spent a great deal of time and effort teaching us about engineering and instilled in me an increasing and life-long interest in turbomachinery. This would not have been possible without the University of Liverpool's award of the W. R. Pickup Foundation Scholarship supporting me as a university student, opening doors of opportunity that changed my life.

Also, I give my most grateful thanks to Professor (now Sir) John H. Horlock for nurturing my interest in the wealth of mysteries concerning the flows through compressors and turbine blades during his tenure of the Harrison Chair of Mechanical Engineering at the University of Liverpool. At an early stage of the sixth edition some deep and helpful discussions of possible additions to the new edition took place with Emeritus Professor John P. Gostelow (a former undergraduate student of mine). There are also many members of staff in the Department of Mechanical Engineering during my career who helped and instructed me for which I am grateful.

Last, but by no means least, to my wife Rosaleen, whose patient support enabled me to meet this new edition to be prepared.

S. Larry Dixon

I would like to thank the University of Cambridge, Department of Engineering, where I have been a student, researcher, and now lecturer. Many people there have contributed to my development as an academic and engineer. Of particular importance is Professor John Young who initiated my enthusiasm for thermofluids through his excellent teaching of the subject in college supervisions. I am also very grateful to Rolls-Royce plc, where I worked for several years. I learned a lot about compressor and turbine aerodynamics from my colleagues there and they continue to support me in my research activities.

As a lecturer in turbomachinery there is no better place to be based than the Whittle Laboratory. I would like to thank the members of the lab, past and present, for their support and all they have taught me. I would like to make a special mention of Dr. Tom Hynes, my Ph.D. supervisor, for encouraging my return to academia from industry and for handing over the teaching of a turbomachinery course to me when I started as a lecturer as this has helped me build up the knowledge needed for this book. Since starting as a lecturer, Dr. Rob Miller has been a great friend and colleague and I would like to thank him for the sound advice he has given on many technical, professional, and personal matters.

King's College, Cambridge, has provided me with accommodation and an environment where I have met many exceptional people. I would like to thank all the fantastic staff there who have given their help and support throughout the preparation of this book. During the spring of 2009 I spent a sabbatical in Spain, where I worked on parts of this book. I am very grateful to Professor Jose Salva and the Propulsion Group within La Universidad Politecnica de Madrid for their hospitality during this time.

Finally, special personal thanks go to my parents, Hazel and Alan for all they have done for me. I would like to dedicate my work on this book to my wife Gisella for her love and happiness.

Cesare A. Hall

List of Symbols

A	area
a	sonic velocity
\bar{a}, a'	axial-flow induction factor, tangential flow induction factor
b	axial chord length, passage width, maximum camber
C_c, C_f	chordwise and tangential force coefficients
C_L, C_D	lift and drag coefficients
C_p	specific heat at constant pressure, pressure coefficient, pressure rise coefficient
C_v	specific heat at constant volume
C_X, C_Y	axial and tangential force coefficients
c	absolute velocity
c_o	spouting velocity
D	drag force, diameter
DR_{eq}	equivalent diffusion ratio
D_h	hydraulic mean diameter
D_s	specific diameter
DF	diffusion factor
E, e	energy, specific energy
F	force, Prandtl correction factor
F_c	centrifugal force in blade
f	friction factor, frequency, acceleration
g	gravitational acceleration
H	blade height, head
H_E	effective head
H_f	head loss due to friction
H_G	gross head
H_S	net positive suction head (NPSH)
h	specific enthalpy
I	rothalpy
i	incidence angle
J	wind turbine tip–speed ratio
j	wind turbine local blade–speed ratio
K, k	constants
L	lift force, length of diffuser wall
l	blade chord length, pipe length
M	Mach number
m	mass, molecular mass
N	rotational speed, axial length of diffuser
N_S	specific speed (rev)
N_{SP}	power specific speed (rev)
N_{SS}	suction specific speed (rev)

n	number of stages, polytropic index
o	throat width
P	power
p	pressure
p_a	atmospheric pressure
p_v	vapour pressure
Q	heat transfer, volume flow rate
R	reaction, specific gas constant, diffuser radius, stream tube radius
Re	Reynolds number
R_H	reheat factor
R_o	universal gas constant
r	radius
S	entropy, power ratio
s	blade pitch, specific entropy
T	temperature
t	time, thickness
U	blade speed, internal energy
u	specific internal energy
V, v	volume, specific volume
W	work transfer, diffuser width
ΔW	specific work transfer
W_x	shaft work
w	relative velocity
X	axial force
x, y, z	Cartesian coordinate directions
Y	tangential force
Y_p	stagnation pressure loss coefficient
Z	number of blades, Zweifel blade loading coefficient
α	absolute flow angle
β	relative flow angle, pitch angle of blade
Γ	circulation
γ	ratio of specific heats
δ	deviation angle
ε	fluid deflection angle, cooling effectiveness, drag–lift ratio in wind turbines
ζ	enthalpy loss coefficient, incompressible stagnation pressure loss coefficient
η	efficiency
θ	blade camber angle, wake momentum thickness, diffuser half angle
κ	angle subtended by log spiral vane
λ	profile loss coefficient, blade loading coefficient, incidence factor
μ	dynamic viscosity
ν	kinematic viscosity, hub-tip ratio, velocity ratio
ξ	blade stagger angle

ρ	density
σ	slip factor, solidity, Thoma coefficient
σ_b	blade cavitation coefficient
σ_c	centrifugal stress
τ	torque
ϕ	flow coefficient, velocity ratio, wind turbine impingement angle
ψ	stage loading coefficient
Ω	speed of rotation (rad/s)
Ω_S	specific speed (rad)
Ω_{SP}	power specific speed (rad)
Ω_{SS}	suction specific speed (rad)
ω	vorticity

Subscripts

^	non-dimensionalised quantity

Introduction: Basic Principles

Take your choice of those that can best aid your action.

Shakespeare, *Coriolanus*

1.1 DEFINITION OF A TURBOMACHINE

We classify as turbomachines all those devices in which energy is transferred either to, or from, a continuously flowing fluid by the *dynamic action* of one or more moving blade rows. The word *turbo* or *turbinis* is of Latin origin and implies that which spins or whirls around. Essentially, a rotating blade row, a *rotor* or an *impeller* changes the stagnation enthalpy of the fluid moving through it by doing either positive or negative work, depending upon the effect required of the machine. These enthalpy changes are intimately linked with the pressure changes occurring simultaneously in the fluid.

Two main categories of turbomachine are identified: firstly, those that *absorb* power to increase the fluid pressure or head (ducted and unducted fans, compressors, and pumps); secondly, those that *produce* power by expanding fluid to a lower pressure or head (wind, hydraulic, steam, and gas turbines). Figure 1.1 shows, in a simple diagrammatic form, a selection of the many varieties of turbomachines encountered in practice. The reason that so many different types of either pump (compressor) or turbine are in use is because of the almost infinite range of service requirements. Generally speaking, for a given set of operating requirements one type of pump or turbine is best suited to provide optimum conditions of operation.

Turbomachines are further categorised according to the nature of the flow path through the passages of the rotor. When the path of the *through-flow* is wholly or mainly parallel to the axis of rotation, the device is termed an *axial flow turbomachine* [e.g., Figures 1.1(a) and (e)]. When the path of the *through-flow* is wholly or mainly in a plane perpendicular to the rotation axis, the device is termed a *radial flow turbomachine* [e.g., Figure 1.1(c)]. More detailed sketches of radial flow machines are given in Figures 7.3, 7.4, 8.2, and 8.3. *Mixed flow turbomachines* are widely used. The term *mixed flow* in this context refers to the direction of the through-flow at the rotor outlet when both radial and axial velocity components are present in significant amounts. Figure 1.1(b) shows a mixed flow pump and Figure 1.1(d) a mixed flow hydraulic turbine.

One further category should be mentioned. All turbomachines can be classified as either *impulse* or *reaction* machines according to whether pressure changes are absent or present, respectively, in the flow through the rotor. In an impulse machine all the pressure change takes place in one or more nozzles, the fluid being directed onto the rotor. The Pelton wheel, Figure 1.1(f), is an example of an impulse turbine.

**FIGURE 1.1**

Examples of Turbomachines

The main purpose of this book is to examine, through the laws of fluid mechanics and thermodynamics, the means by which the energy transfer is achieved in the chief types of turbomachines, together with the differing behaviour of individual types in operation. Methods of analysing the flow processes differ depending upon the geometrical configuration of the machine, whether the fluid can be regarded as incompressible or not, and whether the machine absorbs or produces work. As far as possible, a unified treatment is adopted so that machines having similar configurations and function are considered together.

1.2 COORDINATE SYSTEM

Turbomachines consist of rotating and stationary blades arranged around a common axis, which means that they tend to have some form of cylindrical shape. It is therefore natural to use a cylindrical polar coordinate system aligned with the axis of rotation for their description and analysis. This coordinate

system is pictured in Figure 1.2. The three axes are referred to as axial x , radial r , and tangential (or circumferential) $r\theta$.

In general, the flow in a turbomachine has components of velocity along all three axes, which vary in all directions. However, to simplify the analysis it is usually assumed that the flow does not vary in the tangential direction. In this case, the flow moves through the machine on *axi symmetric stream surfaces*, as drawn on Figure 1.2(a). The component of velocity along an axi-symmetric stream surface is called the *meridional* velocity,

$$c_m = \sqrt{c_x^2 + c_r^2}. \quad (1.1)$$

In purely axial-flow machines the radius of the flow path is constant and therefore, referring to Figure 1.2(c) the radial flow velocity will be zero and $c_m = c_x$. Similarly, in purely radial flow

FIGURE 1.2

The Co-ordinate System and Flow Velocities within a Turbomachine

machines the axial flow velocity will be zero and $c_m = c_r$. Examples of both of these types of machines can be found in Figure 1.1.

The total flow velocity is made up of the meridional and tangential components and can be written

$$c = \sqrt{c_x^2 + c_r^2 + c_\theta^2} = \sqrt{c_m^2 + c_\theta^2}. \quad (1.2)$$

The swirl, or tangential, angle is the angle between the flow direction and the meridional direction:

$$\alpha = \tan^{-1}(c_\theta/c_m). \quad (1.3)$$

Relative Velocities

The analysis of the flow-field within the rotating blades of a turbomachine is performed in a frame of reference that is stationary relative to the blades. In this frame of reference the flow appears as *steady*, whereas in the absolute frame of reference it would be *unsteady*. This makes any calculations significantly more straightforward, and therefore the use of relative velocities and relative flow quantities is fundamental to the study of turbomachinery.

The relative velocity is simply the absolute velocity minus the local velocity of the blade. The blade has velocity only in the tangential direction, and therefore the relative components of velocity can be written as

$$w_\theta = c_\theta - U, w_x = c_x, w_r = c_r. \quad (1.4)$$

The relative flow angle is the angle between the relative flow direction and the meridional direction:

$$\beta = \tan^{-1}(w_\theta/c_m). \quad (1.5)$$

By combining eqns. (1.3), (1.4), and (1.5) a relationship between the relative and absolute flow angles can be found:

$$\tan \beta = \tan \alpha - U/c_m. \quad (1.6)$$

1.3 THE FUNDAMENTAL LAWS

The remainder of this chapter summarises the basic physical laws of fluid mechanics and thermodynamics, developing them into a form suitable for the study of turbomachines. Following this, some of the more important and commonly used expressions for the efficiency of compression and expansion flow processes are given.

The laws discussed are

- (i) the *continuity of flow equation*;
- (ii) the *first law of thermodynamics* and the *steady flow energy equation*;
- (iii) the *momentum equation*;
- (iv) the *second law of thermodynamics*.

All of these laws are usually covered in first-year university engineering and technology courses, so only the briefest discussion and analysis is given here. Some textbooks dealing comprehensively

**FIGURE 1.3**

Flow Across an Element of Area

with these laws are those written by Çengel and Boles (1994); Douglas, Gasiorek, and Swaffield (1995); Rogers and Mayhew (1992); and Reynolds and Perkins (1977). It is worth remembering that these laws are completely general; they are independent of the nature of the fluid or whether the fluid is compressible or incompressible.

1.4 THE EQUATION OF CONTINUITY

Consider the flow of a fluid with density ρ , through the element of area dA , during the time interval dt . Referring to Figure 1.3, if c is the stream velocity the elementary mass is $dm = \rho c dt dA \cos \theta$, where θ is the angle subtended by the normal of the area element to the stream direction. The element of area perpendicular to the flow direction is $dA_n = dA \cos \theta$ and so $dm = \rho c dA_n dt$. The elementary rate of mass flow is therefore

$$\dot{dm} = \frac{dm}{dt} = \rho c dA_n. \quad (1.7)$$

Most analyses in this book are limited to one-dimensional steady flows where the velocity and density are regarded as constant across each section of a duct or passage. If A_{n1} and A_{n2} are the areas normal to the flow direction at stations 1 and 2 along a passage respectively, then

$$\dot{m} = \rho_1 c_1 A_{n1} = \rho_2 c_2 A_{n2} = \rho c A_n, \quad (1.8)$$

since there is no accumulation of fluid within the control volume.

1.5 THE FIRST LAW OF THERMODYNAMICS

The *first law of thermodynamics* states that, if a system is taken through a complete cycle during which heat is supplied and work is done, then

$$\oint (dQ - dW) = 0, \quad (1.9)$$

where $\oint dQ$ represents the heat supplied to the system during the cycle and $\oint dW$ the work done by the system during the cycle. The units of heat and work in eqn. (1.9) are taken to be the same.

During a change from state 1 to state 2, there is a change in the energy within the system:

$$E_2 - E_1 = \int_1^2 (dQ - dW), \quad (1.10a)$$

where $E = U + \frac{1}{2}mc^2 + mgz$.

For an infinitesimal change of state,

$$dE = dQ - dW. \quad (1.10b)$$

The Steady Flow Energy Equation

Many textbooks, e.g., Çengel and Boles (1994), demonstrate how the first law of thermodynamics is applied to the steady flow of fluid through a control volume so that the steady flow energy equation is obtained. It is unprofitable to reproduce this proof here and only the final result is quoted. Figure 1.4 shows a control volume representing a turbomachine, through which fluid passes at a steady rate of mass flow \dot{m} , entering at position 1 and leaving at position 2. Energy is transferred from the fluid to the blades of the turbomachine, positive work being done (via the shaft) at the rate \dot{W}_x . In the general case positive heat transfer takes place at the rate \dot{Q} , from the surroundings to the control volume. Thus, with this sign convention the steady flow energy equation is

$$\dot{Q} - \dot{W}_x = \dot{m} \left[(h_2 - h_1) + \frac{1}{2}(c_2^2 - c_1^2) + g(z_2 - z_1) \right], \quad (1.11)$$

where h is the specific enthalpy, $\frac{1}{2}c^2$, the kinetic energy per unit mass and gz , the potential energy per unit mass.

For convenience, the specific enthalpy, h , and the kinetic energy, $\frac{1}{2}c^2$, are combined and the result is called the *stagnation enthalpy*:

$$h_0 = h + \frac{1}{2}c^2. \quad (1.12)$$

Apart from hydraulic machines, the contribution of the $g(z_2 - z_1)$ term in eqn. (1.11) is small and can usually be ignored. In this case, eqn. (1.11) can be written as

$$\dot{Q} - \dot{W}_x = \dot{m}(h_{02} - h_{01}). \quad (1.13)$$

FIGURE 1.4

Control Volume Showing Sign Convention for Heat and Work Transfers

The stagnation enthalpy is therefore constant in any flow process that does not involve a work transfer or a heat transfer. Most turbomachinery flow processes are adiabatic (or very nearly so) and it is permissible to write $\dot{Q} = 0$. For work producing machines (turbines) $\dot{W}_x > 0$, so that

$$\dot{W}_x = \dot{W}_t = \dot{m}(h_{01} - h_{02}). \quad (1.14)$$

For work absorbing machines (compressors) $\dot{W}_x < 0$, so that it is more convenient to write

$$\dot{W}_c = -\dot{W}_x = \dot{m}(h_{02} - h_{01}). \quad (1.15)$$

1.6 THE MOMENTUM EQUATION

One of the most fundamental and valuable principles in mechanics is *Newton's second law of motion*. The momentum equation relates the sum of the external forces acting on a fluid element to its acceleration, or to the rate of change of momentum in the direction of the resultant external force. In the study of turbomachines many applications of the momentum equation can be found, e.g., the force exerted upon a blade in a compressor or turbine cascade caused by the deflection or acceleration of fluid passing the blades.

Considering a system of mass m , the sum of all the body and surface forces acting on m along some arbitrary direction x is equal to *the time rate of change of the total x -momentum of the system*, i.e.,

$$\sum F_x = \frac{d}{dt}(mc_x). \quad (1.16a)$$

For a control volume where fluid enters steadily at a uniform velocity c_{x1} and leaves steadily with a uniform velocity c_{x2} , then

$$\sum F_x = \dot{m}(c_{x2} - c_{x1}). \quad (1.16b)$$

Equation (1.16b) is the one-dimensional form of the steady flow momentum equation.

Moment of Momentum

In dynamics useful information can be obtained by employing Newton's second law in the form where it applies to the moments of forces. This form is of central importance in the analysis of the energy transfer process in turbomachines.

For a system of mass m , the vector sum of the moments of all external forces acting on the system about some arbitrary axis A – A fixed in space is equal to the time rate of change of angular momentum of the system about that axis, i.e.,

$$\tau_A = m \frac{d}{dt}(rc_\theta), \quad (1.17a)$$

where r is distance of the mass centre from the axis of rotation measured along the normal to the axis and c_θ the velocity component mutually perpendicular to both the axis and radius vector r .

For a control volume the *law of moment of momentum* can be obtained. Figure 1.5 shows the control volume enclosing the rotor of a generalised turbomachine. Swirling fluid enters the control volume

**FIGURE 1.5**

Control Volume for a Generalised Turbomachine

at radius r_1 with tangential velocity $c_{\theta 1}$ and leaves at radius r_2 with tangential velocity $c_{\theta 2}$. For one-dimensional steady flow,

$$\tau_A = \dot{m}(r_2 c_{\theta 2} - r_1 c_{\theta 1}), \quad (1.17b)$$

which states that the sum of the moments of the external forces acting on fluid temporarily occupying the control volume is equal to the net time rate of efflux of angular momentum from the control volume.

The Euler Work Equation

For a pump or compressor rotor running at angular velocity Ω , the rate at which the rotor does work on the fluid is

$$\tau_A \Omega = \dot{m}(U_2 c_{\theta 2} - U_1 c_{\theta 1}), \quad (1.18a)$$

where the blade speed $U = \Omega r$.

Thus, the work done on the fluid per unit mass or specific work is

$$\Delta W_c = \frac{\dot{W}_c}{\dot{m}} = \frac{\tau_A \Omega}{\dot{m}} = U_2 c_{\theta 2} - U_1 c_{\theta 1} > 0. \quad (1.18b)$$

This equation is referred to as *Euler's pump equation*.

For a turbine the fluid does work *on* the rotor and the sign for work is then reversed. Thus, the specific work is

$$\Delta W_t = \frac{\dot{W}_t}{\dot{m}} = U_1 c_{\theta 1} - U_2 c_{\theta 2} > 0. \quad (1.18c)$$

Equation (1.18c) is referred to as *Euler's turbine equation*.

Note that, for any adiabatic turbomachine (turbine or compressor), applying the steady flow energy equation, eqn. (1.13), gives

$$\Delta W_x = (h_{01} - h_{02}) = U_1 c_{\theta 1} - U_2 c_{\theta 2}. \quad (1.19a)$$

Alternatively, this can be written as

$$\Delta h_0 = \Delta(U c_\theta). \quad (1.19b)$$

Equations (1.19a) and (1.19b) are the general forms of the *Euler work equation*. By considering the assumptions used in its derivation, this equation can be seen to be valid for adiabatic flow for any streamline through the blade rows of a turbomachine. It is applicable to both viscous and inviscid flow, since the torque provided by the fluid on the blades can be exerted by pressure forces or frictional forces. It is strictly valid only for steady flow but it can also be applied to time-averaged unsteady flow provided the averaging is done over a long enough time period. In all cases, all of the torque from the fluid must be transferred to the blades. Friction on the hub and casing of a turbomachine can cause local changes in angular momentum that are not accounted for in the Euler work equation.

Note that for any stationary blade row, $U = 0$ and therefore $h_0 = \text{constant}$. This is to be expected since a stationary blade cannot transfer any work to or from the fluid.

Rothalpy and Relative Velocities

The Euler work equation, eqn. (1.19), can be rewritten as

$$I = h_0 - U c_\theta, \quad (1.20a)$$

where I is a constant along the streamlines through a turbomachine. The function I has acquired the widely used name *rothalpy*, a contraction of rotational stagnation enthalpy, and is a fluid mechanical property of some importance in the study of flow within rotating systems. The rothalpy can also be written in terms of the static enthalpy as

$$I = h + \frac{1}{2} c^2 - U c_\theta. \quad (1.20b)$$

The Euler work equation can also be written in terms of relative quantities for a rotating frame of reference. The relative tangential velocity, as given in eqn. (1.4), can be substituted in eqn. (1.20b) to produce

$$I = h + \frac{1}{2} (w^2 + U^2 + 2Uw_\theta) - U(w_\theta + U) = h + \frac{1}{2} w^2 - \frac{1}{2} U^2. \quad (1.21a)$$

Defining a relative stagnation enthalpy as $h_{0,\text{rel}} = h + \frac{1}{2} w^2$, eqn. (1.21a) can be simplified to

$$I = h_{0,\text{rel}} - \frac{1}{2} U^2. \quad (1.21b)$$

This final form of the Euler work equation shows that, for rotating blade rows, the relative stagnation enthalpy is constant through the blades provided the blade speed is constant. In other words, $h_{0,\text{rel}} = \text{constant}$, if the radius of a streamline passing through the blades stays the same. This result is important for analysing turbomachinery flows in the relative frame of reference.

1.7 THE SECOND LAW OF THERMODYNAMICS—ENTROPY

The *second law of thermodynamics*, developed rigorously in many modern thermodynamic textbooks, e.g., Çengel and Boles (1994), Reynolds and Perkins (1977), and Rogers and Mayhew (1992), enables the concept of entropy to be introduced and ideal thermodynamic processes to be defined.

An important and useful corollary of the second law of thermodynamics, known as the *inequality of Clausius*, states that, for a system passing through a cycle involving heat exchanges,

$$\oint \frac{dQ}{T} \leq 0, \quad (1.22a)$$

where dQ is an element of heat transferred to the system at an absolute temperature T . If all the processes in the cycle are reversible, then $dQ = dQ_R$, and the equality in eqn. (1.22a) holds true, i.e.,

$$\oint \frac{dQ_R}{T} = 0. \quad (1.22b)$$

The property called *entropy*, for a finite change of state, is then defined as

$$S_2 - S_1 = \int_1^2 \frac{dQ_R}{T}. \quad (1.23a)$$

For an incremental change of state

$$dS = mds = \frac{dQ_R}{T}, \quad (1.23b)$$

where m is the mass of the system.

With steady one-dimensional flow through a control volume in which the fluid experiences a change of state from condition 1 at entry to 2 at exit,

$$\int_1^2 \frac{d\dot{Q}}{T} \leq \dot{m}(s_2 - s_1). \quad (1.24a)$$

Alternatively, this can be written in terms of an entropy production due to irreversibility, ΔS_{irrev} :

$$\dot{m}(s_2 - s_1) = \int_1^2 \frac{d\dot{Q}}{T} + \Delta S_{\text{irrev}}. \quad (1.24b)$$

If the process is adiabatic, $d\dot{Q} = 0$, then

$$s_2 \geq s_1. \quad (1.25)$$

If the process is *reversible* as well, then

$$s_2 = s_1. \quad (1.26)$$

Thus, for a flow undergoing a process that is both adiabatic and reversible, the entropy will remain unchanged (this type of process is referred to as *isentropic*). Since turbomachinery is usually adiabatic, or close to adiabatic, an isentropic compression or expansion represents the best possible process that can be achieved. To maximize the efficiency of a turbomachine, the irreversible entropy production ΔS_{irrev} must be minimized, and this is a primary objective of any design.

Several important expressions can be obtained using the preceding definition of *entropy*. For a system of mass m undergoing a reversible process $dQ = dQ_R = mTds$ and $dW = dW_R = mpdv$. In the absence of motion, gravity, and other effects the first law of thermodynamics, eqn. (1.10b) becomes

$$Tds = du + pdv. \quad (1.27)$$

With $h = u + pv$, then $dh = du + p dv + v dp$, and eqn. (1.27) then gives

$$T ds = dh - v dp. \quad (1.28)$$

Equations (1.27) and (1.28) are extremely useful forms of the second law of thermodynamics because the equations are written only in terms of properties of the system (there are no terms involving Q or W). These equations can therefore be applied to a system undergoing any process.

Entropy is a particularly useful property for the analysis of turbomachinery. Any creation of entropy in the flow path of a machine can be equated to a certain amount of “lost work” and thus a loss in efficiency. The value of entropy is the same in both the absolute and relative frames of reference (see Figure 1.7 later) and this means it can be used to track the sources of inefficiency through all the rotating and stationary parts of a machine. The application of entropy to account for lost performance is very powerful and will be demonstrated in later sections.

1.8 BERNOULLI'S EQUATION

Consider the steady flow energy equation, eqn. (1.11). For adiabatic flow, with no work transfer,

$$(h_2 - h_1) + \frac{1}{2}(c_2^2 - c_1^2) + g(z_2 - z_1) = 0. \quad (1.29)$$

If this is applied to a control volume whose thickness is infinitesimal in the stream direction (Figure 1.6), the following differential form is derived:

$$dh + c dc + g dz = 0. \quad (1.30)$$

If there are no shear forces acting on the flow (no mixing or friction), then the flow will be isentropic and, from eqn. (1.28), $dh = v dp = dp/\rho$, giving

$$\frac{1}{\rho} dp + c dc + g dz = 0. \quad (1.31a)$$

FIGURE 1.6

Control Volume in a Streaming Fluid

Equation (1.31) is often referred to as the *one-dimensional form* of Euler's equation of motion. Integrating this equation in the stream direction we obtain

$$\int_1^2 \frac{1}{\rho} dp + \frac{1}{2}(c_2^2 - c_1^2) + g(z_2 - z_1) = 0, \quad (1.31b)$$

which is Bernoulli's equation. For an incompressible fluid, ρ is constant and eqn. (1.31b) becomes

$$\frac{1}{\rho}(p_{02} - p_{01}) + g(z_2 - z_1) = 0, \quad (1.31c)$$

where the stagnation pressure for an incompressible fluid is $p_0 = p + \frac{1}{2}\rho c^2$.

When dealing with hydraulic turbomachines, the term *head*, H , occurs frequently and describes the quantity $z + p_0/(\rho g)$. Thus, eqn. (1.31c) becomes

$$H_2 - H_1 = 0. \quad (1.31d)$$

If the fluid is a gas or vapour, the change in gravitational potential is generally negligible and eqn. (1.31b) is then

$$\int_1^2 \frac{1}{\rho} dp + \frac{1}{2}(c_2^2 - c_1^2) = 0. \quad (1.31e)$$

Now, if the gas or vapour is subject to only small pressure changes the fluid density is sensibly constant and integration of eqn. (1.31e) gives

$$p_{02} = p_{01} = p_0, \quad (1.31f)$$

i.e., the stagnation pressure is constant (it is shown later that this is also true for a *compressible isentropic process*).

1.9 COMPRESSIBLE FLOW RELATIONS

The Mach number of a flow is defined as the velocity divided by the local speed of sound. For a perfect gas, such as air, the Mach number can be written as

$$M = \frac{c}{a} = \frac{c}{\sqrt{\gamma RT}}. \quad (1.32)$$

Whenever the Mach number in a flow exceeds about 0.3, the flow becomes compressible, and the fluid density can no longer be considered as constant. High power turbomachines require high flow rates and high blade speeds and this inevitably leads to compressible flow. The static and stagnation quantities in the flow can be related using functions of the local Mach number and these are derived later.

Starting with the definition of stagnation enthalpy, $h_0 = h + \frac{1}{2}c^2$, this can be rewritten for a perfect gas as

$$C_p T_0 = C_p T + \frac{c^2}{2} = C_p T + \frac{M^2 \gamma RT}{2}. \quad (1.33a)$$

Given that $\gamma R = (\gamma - 1)C_p$, eqn. (1.33a) can be simplified to

$$\frac{T_0}{T} = 1 + \frac{\gamma - 1}{2} M^2. \quad (1.33b)$$

The stagnation pressure in a flow is the static pressure that is measured if the flow is brought *isentropically* to rest. From eqn. (1.28), for an isentropic process $dh = dp/\rho$. If this is combined with the equation of state for a perfect gas, $p = \rho RT$, the following equation is obtained:

$$\frac{dp}{p} = \frac{C_p}{R} \frac{dT}{T} = \frac{dT}{T} \frac{\gamma}{\gamma - 1} \quad (1.34)$$

This can be integrated between the static and stagnation conditions to give the following compressible flow relation between the stagnation and static pressure:

$$\frac{p_0}{p} = \left(\frac{T_0}{T} \right)^{\gamma/(\gamma-1)} = \left(1 + \frac{\gamma-1}{2} M^2 \right)^{\gamma/(\gamma-1)}. \quad (1.35)$$

Equation (1.34) can also be integrated along a streamline between any two arbitrary points 1 and 2 within an isentropic flow. In this case, the stagnation temperatures and pressures are related:

$$\frac{p_{02}}{p_{01}} = \left(\frac{T_{02}}{T_{01}} \right)^{\gamma/(\gamma-1)}. \quad (1.36)$$

If there is no heat or work transfer to the flow, $T_0 = \text{constant}$. Hence, eqn. (1.36) shows that, in isentropic flow with no work transfer, $p_{02} = p_{01} = \text{constant}$, which was shown to be the case for incompressible flow in eqn. (1.31f).

Combining the equation of state, $p = \rho RT$ with eqns. (1.33b) and (1.35) the corresponding relationship for the stagnation density is obtained:

$$\frac{\rho_0}{\rho} = \left(1 + \frac{\gamma-1}{2} M^2 \right)^{1/(\gamma-1)}. \quad (1.37)$$

Arguably the most important compressible flow relationship for turbomachinery is the one for non-dimensional mass flow rate, sometimes referred to as *capacity*. It is obtained by combining eqns. (1.33b), (1.35), and (1.37) with continuity, eqn. (1.8):

$$\frac{\dot{m} \sqrt{C_p T_0}}{A_n p_0} = \frac{\gamma}{\sqrt{\gamma-1}} M \left(1 + \frac{\gamma-1}{2} M^2 \right)^{-\frac{1}{2} \left(\frac{\gamma+1}{\gamma-1} \right)}. \quad (1.38)$$

This result is important since it can be used to relate the flow properties at different points within a compressible flow turbomachine. The application of eqn. (1.38) is demonstrated in Chapter 3.

Note that the compressible flow relations given previously can be applied in the relative frame of reference for flow within rotating blade rows. In this case relative stagnation properties and relative Mach numbers are used:

$$\frac{p_{0,\text{rel}}}{p}, \frac{T_{0,\text{rel}}}{T}, \frac{\rho_{0,\text{rel}}}{\rho}, \frac{\dot{m} \sqrt{C_p T_{0,\text{rel}}}}{A p_{0,\text{rel}}} = f(M_{\text{rel}}). \quad (1.39)$$

Figure 1.7 shows the relationship between stagnation and static conditions on a temperature–entropy diagram, in which the temperature differences have been exaggerated for clarity. This shows the relative stagnation properties as well as the absolute properties for a single point in a flow. Note that all of the conditions have the same entropy because the stagnation states are defined using an isentropic process. The pressures and temperatures are related using eqn. (1.35).

Variation of Gas Properties with Temperature

The thermodynamic properties of a gas, C_p and γ , are dependent upon its temperature level, and some account must be taken of this effect. To illustrate this dependency the variation in the values of C_p and γ with the temperature for air are shown in Figure 1.8. In the calculation of expansion or compression processes in turbomachines the normal practice is to use weighted mean values for C_p and γ according to the mean temperature of the process. Accordingly, in all problems in this book values have been selected for C_p and γ appropriate to the gas and the temperature range.

Variation of Gas Properties with Temperature for Dry Air (data from Rogers and Mayhew, 1995)

1.10 DEFINITIONS OF EFFICIENCY

A large number of efficiency definitions are included in the literature of turbomachines and most workers in this field would agree there are too many. In this book only those considered to be important and useful are included.

Efficiency of Turbines

Turbines are designed to convert the available energy in a flowing fluid into useful mechanical work delivered at the coupling of the output shaft. The efficiency of this process, the *overall efficiency* η_0 , is a performance factor of considerable interest to both designer and user of the turbine. Thus,

$$\eta_0 = \frac{\text{mechanical energy available at coupling of output shaft in unit time}}{\text{maximum energy difference possible for the fluid in unit time}}.$$

Mechanical energy losses occur between the turbine rotor and the output shaft coupling as a result of the work done against friction at the bearings, glands, etc. The magnitude of this loss as a fraction of the total energy transferred to the rotor is difficult to estimate as it varies with the size and individual design of turbomachine. For small machines (several kilowatts) it may amount to 5% or more, but for medium and large machines this loss ratio may become as little as 1%. A detailed consideration of the mechanical losses in turbomachines is beyond the scope of this book and is not pursued further.

The *isentropic efficiency* η_t or *hydraulic efficiency* η_h for a turbine is, in broad terms,

$$\eta_t \text{ (or } \eta_h) = \frac{\text{mechanical energy supplied to the rotor in unit time}}{\text{maximum energy difference possible for the fluid in unit time}}.$$

Comparing these definitions it is easily deduced that the *mechanical efficiency* η_m , which is simply the ratio of shaft power to rotor power, is

$$\eta_m = \eta_0 / \eta_t \text{ (or } \eta_0 / \eta_h). \quad (1.40)$$

The preceding isentropic efficiency definition can be concisely expressed in terms of the work done by the fluid passing through the turbine:

$$\eta_t \text{ (or } \eta_h) = \frac{\text{actual work}}{\text{ideal (maximum) work}} = \frac{\Delta W_x}{\Delta W_{\max}}. \quad (1.41)$$

The *actual work* is unambiguous and straightforward to determine from the steady flow energy equation, eqn. (1.11). For an adiabatic turbine, using the definition of stagnation enthalpy,

$$\Delta W_x = \dot{W}_x / \dot{m} = (h_{01} - h_{02}) + g(z_1 - z_2).$$

The *ideal work* is slightly more complicated as it depends on how the ideal process is defined. The process that gives maximum work will always be an isentropic expansion, but the question is one of how to define the exit state of the ideal process relative to the actual process. In the following paragraphs the different definitions are discussed in terms of to what type of turbine they are applied.

Steam and Gas Turbines

Figure 1.9(a) shows a Mollier diagram representing the expansion process through an adiabatic turbine. Line 1–2 represents the actual expansion and line 1–2s the ideal or reversible expansion. The fluid velocities at entry to and exit from a turbine may be quite high and the corresponding kinetic energies significant. On the other hand, for a compressible fluid the potential energy terms are usually negligible. Hence, the *actual* turbine rotor *specific work* is

$$\Delta W_x = \dot{W}_x / \dot{m} = h_{01} - h_{02} = (h_1 - h_2) + \frac{1}{2}(c_1^2 - c_2^2).$$

There are two main ways of expressing the isentropic efficiency, the choice of definition depending largely upon whether the *exit kinetic energy* is usefully employed or is wasted. If the exhaust kinetic energy is useful, then the ideal expansion is to the same stagnation (or total) pressure as the actual process. The ideal work output is therefore that obtained between state points 01 and 02s,

$$\Delta W_{\max} = \dot{W}_{\max} / \dot{m} = h_{01} - h_{02s} = (h_1 - h_{2s}) + \frac{1}{2}(c_1^2 - c_{2s}^2).$$

The relevant adiabatic efficiency, η , is called the *total-to-total efficiency* and it is given by

$$\eta_{tt} = \Delta W_x / \Delta W_{\max} = (h_{01} - h_{02}) / (h_{01} - h_{02s}). \quad (1.42a)$$

If the difference between the inlet and outlet kinetic energies is small, i.e., $\frac{1}{2}c_1^2 \cong \frac{1}{2}c_2^2$, then

$$\eta_{tt} = (h_1 - h_2) / (h_1 - h_{2s}). \quad (1.42b)$$

An example where the exhaust kinetic energy is not wasted is from the last stage of an aircraft gas turbine where it contributes to the jet propulsive thrust. Likewise, the exit kinetic energy from one stage of a multistage turbine where it can be used in the following stage provides another example.

FIGURE 1.9

Enthalpy–Entropy Diagrams for the Flow Through an Adiabatic Turbine and an Adiabatic Compressor

If, instead, the exhaust kinetic energy cannot be usefully employed and is entirely wasted, the ideal expansion is to the same static pressure as the actual process with zero exit kinetic energy. The ideal work output in this case is that obtained between state points 01 and 2s:

$$\Delta W_{\max} = \dot{W}_{\max}/\dot{m} = h_{01} - h_{2s} = (h_1 - h_{2s}) + \frac{1}{2}c_1^2.$$

The relevant adiabatic efficiency is called the *total-to-static efficiency* η_{ts} and is given by

$$\eta_{ts} = \Delta W_x / \Delta W_{\max} = (h_{01} - h_{02}) / (h_{01} - h_{2s}). \quad (1.43a)$$

If the difference between inlet and outlet kinetic energies is small, eqn. (1.43a) becomes

$$\eta_{ts} = (h_1 - h_2) / \left(h_1 - h_{2s} + \frac{1}{2}c_1^2 \right). \quad (1.43b)$$

A situation where the outlet kinetic energy is wasted is a turbine exhausting directly to the surroundings rather than through a diffuser. For example, auxiliary turbines used in rockets often have no exhaust diffusers because the disadvantages of increased mass and space utilisation are greater than the extra propellant required as a result of reduced turbine efficiency.

By comparing eqns. (1.42) and (1.43) it is clear that the total-to-static efficiency will always be lower than the total-to-total efficiency. The total-to-total efficiency relates to the internal losses (entropy creation) within the turbine, whereas the total-to-static efficiency relates to the internal losses plus the wasted kinetic energy.

Hydraulic Turbines

The turbine hydraulic efficiency is a form of the total-to-total efficiency expressed previously. The steady flow energy equation (eqn. 1.11) can be written in differential form for an adiabatic turbine as

$$d\dot{W}_x = \dot{m} \left[dh + \frac{1}{2}d(c^2) + g dz \right].$$

For an isentropic process, $Tds = 0 = dh - dp/\rho$. The maximum work output for an expansion to the same exit static pressure, kinetic energy, and height as the actual process is therefore

$$\dot{W}_{\max} = \dot{m} \left[\int_1^2 \frac{1}{\rho} dp + \frac{1}{2}(c_1^2 - c_2^2) + g(z_1 - z_2) \right].$$

For an incompressible fluid, the maximum work output from a hydraulic turbine (ignoring frictional losses) can be written

$$\dot{W}_{\max} = \dot{m} \left[\frac{1}{\rho}(p_1 - p_2) + \frac{1}{2}(c_1^2 - c_2^2) + g(z_1 - z_2) \right] = \dot{m}g(H_1 - H_2),$$

where $gH = p/\rho + \frac{1}{2}c^2 + gz$ and $\dot{m} = \rho Q$.

The turbine hydraulic efficiency, η_h , is the work supplied by the rotor divided by the hydrodynamic energy difference of the fluid, i.e.,

$$\eta_h = \frac{\dot{W}_x}{\dot{W}_{\max}} = \frac{\Delta W_x}{g[H_1 - H_2]}. \quad (1.44)$$

Efficiency of Compressors and Pumps

The isentropic *efficiency*, η_c , of a compressor or the *hydraulic efficiency* of a pump, η_h , is broadly defined as

$$\eta_c \text{ (or } \eta_h) = \frac{\text{useful (hydrodynamic) energy input to fluid in unit time}}{\text{power input to rotor}}$$

The power input to the rotor (or impeller) is always less than the power supplied at the coupling because of external energy losses in the bearings, glands, etc. Thus, the overall efficiency of the compressor or pump is

$$\eta_o = \frac{\text{useful (hydrodynamic) energy input to fluid in unit time}}{\text{power input to coupling of shaft}}.$$

Hence, the mechanical efficiency is

$$\eta_m = \eta_o / \eta_c \text{ (or } \eta_o / \eta_h). \quad (1.45)$$

For a complete adiabatic compression process going from state 1 to state 2, the specific work input is

$$\Delta W_c = (h_{02} - h_{01}) + g(z_2 - z_1).$$

Figure 1.9(b) shows a Mollier diagram on which the actual compression process is represented by the state change 1–2 and the corresponding ideal process by 1–2s. For an adiabatic compressor in which potential energy changes are negligible, the most meaningful efficiency is the total-to-total efficiency, which can be written as

$$\eta_c = \frac{\text{ideal (minimum) work input}}{\text{actual work input}} = \frac{h_{02s} - h_{01}}{h_{02} - h_{01}}. \quad (1.46a)$$

If the difference between inlet and outlet kinetic energies is small, $\frac{1}{2}c_1^2 \cong \frac{1}{2}c_2^2$ then

$$\eta_c = \frac{h_{2s} - h_1}{h_2 - h_1}. \quad (1.46b)$$

For *incompressible* flow, the minimum work input is given by

$$\Delta W_{\min} = \dot{W}_{\min} / \dot{m} = \left[(p_2 - p_1) / \rho + \frac{1}{2}(c_2^2 - c_1^2) + g(z_2 - z_1) \right] = g[H_2 - H_1].$$

For a pump the hydraulic efficiency is therefore defined as

$$\eta_h = \frac{\dot{W}_{\min}}{\dot{W}_c} = \frac{g[H_2 - H_1]}{\Delta W_c}. \quad (1.47)$$

1.11 SMALL STAGE OR POLYTROPIC EFFICIENCY

The isentropic *efficiency* described in the preceding section, although fundamentally valid, can be misleading if used for comparing the efficiencies of turbomachines of differing pressure ratios. Now, any turbomachine may be regarded as being composed of a large number of very small stages, irrespective

of the actual number of stages in the machine. If each small stage has the same efficiency, then the isentropic efficiency of the whole machine will be different from the small stage efficiency, the difference depending upon the pressure ratio of the machine. This perhaps rather surprising result is a manifestation of a simple thermodynamic effect concealed in the expression for isentropic efficiency and is made apparent in the following argument.

Compression Process

Figure 1.10 shows an enthalpy–entropy diagram on which adiabatic compression between pressures p_1 and p_2 is represented by the change of state between points 1 and 2. The corresponding reversible process is represented by the isentropic line 1 to 2s. It is assumed that the compression process may be divided into a large number of small stages of equal efficiency η_p . For each small stage the actual work input is δW and the corresponding ideal work in the isentropic process is δW_{\min} . With the notation of Figure 1.10,

$$\eta_p = \frac{\delta W_{\min}}{\delta W} = \frac{h_{xs} - h_1}{h_x - h_1} = \frac{h_{ys} - h_x}{h_y - h_x} = \dots$$

Since each small stage has the same efficiency, then $\eta_p = (\Sigma \delta W_{\min} / \Sigma \delta W)$ is also true.

From the relation $Tds = dh - vdp$, for a constant pressure process, $(\partial h / \partial s)_{p1} = T$. This means that the higher the fluid temperature, the *greater* is the slope of the constant pressure lines on the Mollier diagram. For a gas where h is a function of T , constant pressure lines diverge and the slope of the line

FIGURE 1.10

Compression Process by Small Stages

p_2 is greater than the slope of line p_1 at the same value of entropy. At equal values of T , constant pressure lines are of equal slope as indicated in Figure 1.10. For the special case of a *perfect gas* (where C_p is constant), $C_p(dT/ds) = T$ for a constant pressure process. Integrating this expression results in the equation for a constant pressure line, $s = C_p \log T + \text{constant}$.

Returning now to the more general case, since

$$\Sigma dW = \{(h_x - h_1) + (h_y - h_x) + \dots\} = (h_2 - h_1),$$

then

$$\eta_p = [(h_{xs} - h_1) + (h_{ys} - h_x) + \dots] / (h_2 - h_1).$$

The adiabatic efficiency of the *whole* compression process is

$$\eta_c = (h_{2s} - h_1) / (h_2 - h_1).$$

Due to the divergence of the constant pressure lines

$$\{(h_{xs} - h_1) + (h_{ys} - h_x) + \dots\} > (h_{2s} - h_1),$$

i.e.,

$$\Sigma \delta W_{\min} > W_{\min}.$$

Therefore,

$$\eta_p > \eta_c.$$

Thus, for a compression process the isentropic efficiency of the machine is *less* than the small stage efficiency, the difference being dependent upon the divergence of the constant pressure lines. Although the foregoing discussion has been in terms of static states it also applies to stagnation states since these are related to the static states via isentropic processes.

Small Stage Efficiency for a Perfect Gas

An explicit relation can be readily derived for a perfect gas (C_p is constant) between small stage efficiency, the overall isentropic efficiency and the pressure ratio. The analysis is for the limiting case of an infinitesimal compressor stage in which the incremental change in pressure is dp as indicated in Figure 1.11. For the actual process the incremental enthalpy rise is dh and the corresponding ideal enthalpy rise is dh_{is} .

The polytropic efficiency for the small stage is

$$\eta_p = \frac{dh_{is}}{dh} = \frac{v dp}{C_p dT}, \quad (1.48)$$

since for an isentropic process $T ds = 0 = dh_{is} - v dp$. Substituting $v = RT/p$ into eqn. (1.48) and using $C_p = \gamma R / (\gamma - 1)$ gives

$$\frac{dT}{T} = \frac{(\gamma - 1)}{\gamma \eta_p} \frac{dp}{p}. \quad (1.49)$$

FIGURE 1.11

Incremental Change of State in a Compression Process

Integrating eqn. (1.49) across the whole compressor and taking equal efficiency for each infinitesimal stage gives

$$\frac{T_2}{T_1} = \left(\frac{p_2}{p_1} \right)^{(\gamma-1)/\eta_p \gamma} \quad (1.50)$$

Now the isentropic efficiency for the whole compression process is

$$\eta_c = (T_{2s} - T_1) / (T_2 - T_1) \quad (1.51)$$

if it is assumed that the velocities at inlet and outlet are equal.

For the *ideal* compression process put $\eta_p = 1$ in eqn. (1.50) and so obtain

$$\frac{T_{2s}}{T_1} = \left(\frac{p_2}{p_1} \right)^{(\gamma-1)/\gamma}, \quad (1.52)$$

which is equivalent to eqn. (1.36). Substituting eqns. (1.50) and (1.52) into eqn. (1.51) results in the expression

$$\eta_c = \left[\left(\frac{p_2}{p_1} \right)^{(\gamma-1)/\gamma} - 1 \right] / \left[\left(\frac{p_2}{p_1} \right)^{(\gamma-1)/\eta_p \gamma} - 1 \right]. \quad (1.53)$$

Values of “overall” isentropic efficiency have been calculated using eqn. (1.53) for a range of pressure ratio and different values of η_p ; these are plotted in Figure 1.12. This figure amplifies the observation made earlier that the isentropic efficiency of a finite compression process is *less* than the efficiency of the small stages. Comparison of the isentropic efficiency of two machines of different pressure ratios is not a valid procedure since, for equal polytropic efficiency, the compressor with the higher pressure ratio is penalised by the *hidden* thermodynamic effect.

**FIGURE 1.12**

Relationship Between Isentropic (Overall) Efficiency, Pressure Ratio, and Small Stage (Polytropic) Efficiency for a Compressor ($\gamma = 1.4$)

Example 1.1

An axial flow air compressor is designed to provide an overall total-to-total pressure ratio of 8 to 1. At inlet and outlet the stagnation temperatures are 300 K and 586.4 K, respectively.

Determine the overall total-to-total efficiency and the polytropic efficiency for the compressor. Assume that γ for air is 1.4.

Solution

From eqn. (1.46), substituting $h = C_p T$, the efficiency can be written as

$$\eta_c = \frac{T_{02s} - T_{01}}{T_{02} - T_{01}} = \frac{\left(\frac{p_{02}}{p_{01}}\right)^{(\gamma-1)/\gamma} - 1}{T_{02}/T_{01} - 1} = \frac{8^{1/3.5} - 1}{586 \times 4/300 - 1} = 0.85.$$

From eqn. (1.50), taking logs of both sides and rearranging, we get

$$\eta_p = \frac{\gamma - 1}{\gamma} \frac{\ln(p_{02}/p_{01})}{\ln(T_{02}/T_{01})} = \frac{1}{3.5} \times \frac{\ln 8}{\ln 1.9547} = 0.8865.$$

Turbine Polytropic Efficiency

A similar analysis to the compression process can be applied to a perfect gas expanding through an adiabatic turbine. For the turbine the appropriate expressions for an expansion, from a state 1 to a state 2, are

FIGURE 1.13

Turbine Isentropic Efficiency against Pressure Ratio for Various Polytropic Efficiencies ($\gamma = 1.4$)

$$\frac{T_2}{T_1} = \left(\frac{p_2}{p_1} \right)^{\eta_p(\gamma-1)/\gamma}, \quad (1.54)$$

$$\eta_t = \left[1 - \left(\frac{p_2}{p_1} \right)^{\eta_p(\gamma-1)/\gamma} \right] / \left[1 - \left(\frac{p_2}{p_1} \right)^{(\gamma-1)/\gamma} \right]. \quad (1.55)$$

The derivation of these expressions is left as an exercise for the student. “Overall” isentropic efficiencies have been calculated for a range of pressure ratios and polytropic efficiencies, and these are shown in Figure 1.13. The most notable feature of these results is that, in contrast with a compression process, for an expansion, isentropic efficiency *exceeds* small stage efficiency.

Reheat Factor

The foregoing relations cannot be applied to steam turbines as vapours do not obey the perfect gas laws. It is customary in steam turbine practice to use a *reheat factor* R_H as a measure of the inefficiency of the complete expansion. Referring to Figure 1.14, the expansion process through an adiabatic turbine from state 1 to state 2 is shown on a Mollier diagram, split into a number of small stages. The reheat factor is defined as

$$R_H = [(h_1 - h_{xs}) + (h_x - h_{ys}) + \dots] / (h_1 - h_{2s}) = (\Sigma \Delta h_{is}) / (h_1 - h_{2s}).$$

Due to the gradual divergence of the constant pressure lines on a Mollier chart, R_H is always greater than unity. The actual value of R_H for a large number of stages will depend upon the position of the expansion line on the Mollier chart and the overall pressure ratio of the expansion. In normal steam turbine practice the value of R_H is usually between 1.03 and 1.08.

**FIGURE 1.14**

Mollier Diagram Showing Expansion Process Through a Turbine Split up into a Number of Small Stages

Now since the isentropic efficiency of the turbine is

$$\eta_t = \frac{h_1 - h_2}{h_1 - h_{2s}} = \frac{h_1 - h_2}{\Sigma \Delta h_{is}} \times \frac{\Sigma \Delta h_{is}}{h_1 - h_{2s}},$$

then

$$\eta_t = \eta_p R_H, \quad (1.56)$$

which establishes the connection between polytropic efficiency, reheat factor and turbine isentropic efficiency.

1.12 THE INHERENT UNSTEADINESS OF THE FLOW WITHIN TURBOMACHINES

It is a less well-known fact often ignored by designers of turbomachinery that turbomachines can only work the way they do because of *flow unsteadiness*. This subject was discussed by Dean (1959), Horlock and Daneshyar (1970), and Greitzer (1986). Here, only a brief introduction to an extensive subject is given.

In the absence of viscosity, the equation for the stagnation enthalpy change of a fluid particle moving through a turbomachine is

$$\frac{Dh_0}{Dt} = \frac{1}{\rho} \frac{\partial p}{\partial t}, \quad (1.57)$$

where D/Dt is the rate of change following the fluid particle. Eqn. (1.57) shows us that any change in stagnation enthalpy of the fluid is a result of unsteady variations in static pressure. In fact, without unsteadiness, no change in stagnation enthalpy is possible and thus no work can be done by the fluid. This is the so-called “*Unsteadiness Paradox*.” Steady approaches can be used to determine the work transfer in a turbomachine, yet the underlying mechanism is fundamentally unsteady.

A physical situation considered by Greitzer is the axial compressor rotor as depicted in Figure 1.15a. The pressure field associated with the blades is such that the pressure increases from the suction surface (S) to the pressure surface (P). This pressure field moves with the blades and is therefore steady in the relative frame of reference. However, for an observer situated at the point* (in the absolute frame of reference), a pressure that varies with time would be recorded, as shown in Figure 1.15b. This unsteady pressure variation is directly related to the blade pressure field via the rotational speed of the blades,

$$\frac{\partial p}{\partial t} = \Omega \frac{\partial p}{\partial \theta} = U \frac{\partial p}{r \partial \theta}. \quad (1.58)$$

Thus, the fluid particles passing through the rotor experience a positive pressure increase with time (i.e., $\partial p / \partial t > 0$) and their stagnation enthalpy is increased.

PROBLEMS

- For the adiabatic expansion of a perfect gas through a turbine, show that the overall efficiency η_t and small stage efficiency η_p are related by

$$\eta_t = (1 - \varepsilon^{\eta_p}) / (1 - \varepsilon),$$

where $\varepsilon = r^{(1-\gamma)/\gamma}$, and r is the expansion pressure ratio, γ is the ratio of specific heats. An axial flow turbine has a small stage efficiency of 86%, an overall pressure ratio of 4.5 to 1 and a mean value of γ equal to 1.333. Calculate the overall turbine efficiency.

- Air is expanded in a multi stage axial flow turbine, the pressure drop across each stage being very small. Assuming that air behaves as a perfect gas with ratio of specific heats γ , derive pressure–temperature relationships for the following processes:
 - reversible adiabatic expansion;
 - irreversible adiabatic expansion, with small stage efficiency η_p ;
 - reversible expansion in which the heat loss in each stage is a constant fraction k of the enthalpy drop in that stage;
 - reversible expansion in which the heat loss is proportional to the absolute temperature T .

Sketch the first three processes on a T, s diagram. If the entry temperature is 1100 K and the pressure ratio across the turbine is 6 to 1, calculate the exhaust temperatures in each of the first three cases. Assume that γ is 1.333, that $\eta_p = 0.85$, and that $k = 0.1$.

- A multistage high-pressure steam turbine is supplied with steam at a stagnation pressure of 7 MPa and a stagnation temperature of 500°C. The corresponding specific enthalpy is

3410 kJ/kg. The steam exhausts from the turbine at a stagnation pressure of 0.7 MPa, the steam having been in a superheated condition throughout the expansion. It can be assumed that the steam behaves like a perfect gas over the range of the expansion and that $\gamma = 1.3$. Given that the turbine flow process has a small-stage efficiency of 0.82, determine

- (i) the temperature and specific volume at the end of the expansion,
- (ii) the reheat factor.

The specific volume of superheated steam is represented by $p\nu = 0.231(h = 1943)$, where p is in kPa, ν is in m^3/kg , and h is in kJ/kg.

4. A 20 MW back-pressure turbine receives steam at 4 MPa and 300°C , exhausting from the last stage at 0.35 MPa. The stage efficiency is 0.85, reheat factor 1.04, and external losses 2% of the actual isentropic enthalpy drop. Determine the rate of steam flow. At the exit from the first stage nozzles, the steam velocity is 244 m/s, specific volume $68.6 \text{ dm}^3/\text{kg}$, mean diameter 762 mm, and steam exit angle 76° measured from the axial direction. Determine the nozzle exit height of this stage.
5. Steam is supplied to the first stage of a five stage pressure-compounded steam turbine at a stagnation pressure of 1.5 MPa and a stagnation temperature of 350°C . The steam leaves the last stage at a stagnation pressure of 7.0 kPa with a corresponding dryness fraction of 0.95. By using a Mollier chart for steam and assuming that the stagnation state point locus is a straight line joining the initial and final states, determine
 - (i) the stagnation conditions between each stage assuming that each stage does the same amount of work;
 - (ii) the total-to-total efficiency of each stage;
 - (iii) the overall total-to-total efficiency and total-to-static efficiency assuming the steam enters the condenser with a velocity of 200 m/s;
 - (iv) the reheat factor based upon stagnation conditions.

Dimensional Analysis: Similitude

If you have known one you have known all.

Terence, *Phormio*

2.1 DIMENSIONAL ANALYSIS AND PERFORMANCE LAWS

The widest comprehension of the general behaviour of all turbomachines is, without doubt, obtained from *dimensional analysis*. This is the formal procedure whereby the group of variables representing some physical situation is reduced to a smaller number of dimensionless groups. When the number of independent variables is not too great, dimensional analysis enables experimental relations between variables to be found with the greatest economy of effort. Dimensional analysis applied to turbomachines has two further important uses: (a) prediction of a prototype's performance from tests conducted on a scale model (similitude); (b) determination of the most suitable type of machine, on the basis of maximum efficiency, for a specified range of head, speed, and flow rate. Several methods of constructing non-dimensional groups have been described by Douglas, Gasiorek, and Swaffield (1995) and Shames (1992), among other authors. The subject of dimensional analysis was made simple and much more interesting by Edward Taylor (1974) in his comprehensive account of the subject. It is assumed here that the basic techniques of forming non-dimensional groups have already been acquired by the student.

Adopting the simple approach of elementary thermodynamics, a control surface of fixed shape, position, and orientation is drawn around the turbomachine (Figure 2.1). Across this boundary, fluid flows steadily, entering at station 1 and leaving at station 2. As well as the flow of fluid there is a flow of work across the control surface, transmitted by the shaft either to, or from, the machine. All details of the flow within the machine can be ignored and only externally observed features such as shaft speed, flow rate, torque, and change in fluid properties across the machine need be considered. To be specific, let the turbomachine be a *pump* (although the analysis could apply to other classes of turbomachine) driven by an electric motor. The speed of rotation N , can be adjusted by altering the current to the motor; the volume flow rate Q , can be *independently* adjusted by means of a throttle valve. For fixed values of the set Q and N , all other variables, such as torque, τ , and head, H , are thereby established. The choice of Q and N as *control variables* is clearly arbitrary and any other pair of independent variables such as τ and H could equally well have been chosen. The important point to recognise is that there are, for this pump, *two* control variables.

If the fluid flowing is changed for another of different density ρ , and viscosity μ , the performance of the machine will be affected. Note also that, for a turbomachine handling compressible fluids, other *fluid properties* are important and are discussed later.

**FIGURE 2.1**

Turbomachine Considered as a Control Volume

So far we have considered only one particular turbomachine, namely a pump of a given size. To extend the range of this discussion, the effect of the *geometric variables* on the performance must now be included. The size of machine is characterised by the impeller diameter D , and the shape can be expressed by a number of length ratios, l_1/D , l_2/D , etc.

2.2 INCOMPRESSIBLE FLUID ANALYSIS

The performance of a turbomachine can now be expressed in terms of the control variables, geometric variables, and fluid properties. For the hydraulic pump it is convenient to regard the net energy transfer gH , the efficiency η , and power supplied P as dependent variables and to write the three functional relationships as

$$gH = f_1 \left(Q, N, D, \rho, \mu, \frac{l_1}{D}, \frac{l_2}{D}, \dots \right), \quad (2.1a)$$

$$\eta = f_2 \left(Q, N, D, \rho, \mu, \frac{l_1}{D}, \frac{l_2}{D}, \dots \right), \quad (2.1b)$$

$$P = f_3 \left(Q, N, D, \rho, \mu, \frac{l_1}{D}, \frac{l_2}{D}, \dots \right), \quad (2.1c)$$

By the procedure of dimensional analysis using the three primary dimensions, mass, length, and time, or alternatively, using three of the independent variables we can form the dimensionless groups. The latter, more direct procedure requires that the variables selected, ρ , N , D , do not of themselves form a dimensionless group. The selection of ρ , N , and D as common factors avoids the appearance of special fluid terms (e.g., μ , Q) in more than one group and allows gH , η , and P to be made explicit. Hence, the three relationships reduce to the following easily verified forms:

Energy transfer coefficient, sometimes called head coefficient

$$\psi = \frac{gH}{(ND)^2} = f_4 \left(\frac{Q}{ND^3}, \frac{\rho ND^2}{\mu}, \frac{l_1}{D}, \frac{l_2}{D}, \dots \right), \quad (2.2a)$$

Efficiency, which is already non-dimensional

$$\eta = f_5\left(\frac{Q}{ND^3}, \frac{\rho ND^2}{\mu}, \frac{l_1}{D}, \frac{l_2}{D}, \dots\right), \quad (2.2b)$$

Power coefficient

$$\hat{P} = \frac{P}{\rho N^3 D^5} = f_6\left(\frac{Q}{ND^3}, \frac{\rho ND^2}{\mu}, \frac{l_1}{D}, \frac{l_2}{D}, \dots\right). \quad (2.2c)$$

The non-dimensional group $Q/(ND^3)$ is a volumetric flow coefficient and $\rho ND^2/\mu$ is a form of Reynolds number, Re. In non-hydraulic flow turbomachines, an alternative to $Q/(ND^3)$ that is frequently used is the velocity (or flow) coefficient $\Phi = c_m/U$, where U is the mean blade speed and c_m the average meridional velocity. Since

$$Q = c_m \times \text{flow area} \propto c_m D^2 \text{ and } U \propto ND,$$

then

$$\frac{Q}{ND^3} \propto \frac{c_m}{U} = \Phi.$$

Both of these non-dimensional groups are usually referred to as a flow coefficient, Φ .

Because of the large number of independent groups of variables on the right-hand side of eqns. (2.2a–c), those relationships are virtually worthless unless certain terms can be discarded. In a family of *geometrically similar* machines l_1/D , l_2/D are constant and may be eliminated forthwith. Furthermore, it is found by experiment that provided $\text{Re} > 2 \times 10^5$, the effects of Re on the performance of turbomachines is small. This is true because at high Re the boundary layers on the blades of a turbomachine are predominantly turbulent and very thin. They therefore have little impact on the global flow-field. Efficiency is the variable that can be most affected by Reynolds number and typically η will rise 1–2% as Re increases an order of magnitude. For turbomachines handling water the kinematic viscosity, $\nu = \mu/\rho$, is very small and, although speed, expressed by ND , may be low the corresponding Reynolds number is still high and its effects may be ignored in a first approximation.

Note that the effects of surface finish have also been ignored in the analysis. At high Reynolds numbers, greater surface roughness tends to increase skin friction losses and thus reduce the efficiency. The effects at lower Reynolds numbers are more complex as the boundary layers may be laminar or undergoing transition to turbulence. Here it is assumed that both the surface finish effects are small and that the Reynolds numbers are high. The functional relationships for geometrically similar hydraulic turbomachines are then

$$\psi = f_4[Q/(ND^3)] \quad (2.3a)$$

$$\eta = f_5[Q/(ND^3)] \quad (2.3b)$$

$$\hat{P} = f_6[Q/(ND^3)]. \quad (2.3c)$$

This is as far as the reasoning of dimensional analysis alone can be taken; the actual *form* of the functions f_4 , f_5 , and f_6 must be ascertained by experiment.

One relation between ψ , Φ , η , and \hat{P} may be immediately stated. For a pump the *net hydraulic power*, P_N equals $\rho Q g H$, which is the minimum shaft power required in the absence of all losses. As shown in Chapter 1, we define pump efficiency $\eta = P_N/P = \rho Q g H/P$. Therefore,

$$P = \frac{1}{\eta} \left(\frac{Q}{ND^3} \right) \frac{gH}{(ND)^2} \rho N^3 D^5. \quad (2.4)$$

Thus, f_6 may be derived from f_4 and f_5 since $\hat{P} = \Phi\psi/\eta$. For a turbine the net hydraulic power P_N supplied is greater than the actual shaft power delivered by the machine and the efficiency $\eta = P/P_N$. This can be rewritten as $\hat{P} = \Phi\psi\eta$ by reasoning similar to the preceding considerations.

2.3 PERFORMANCE CHARACTERISTICS FOR LOW SPEED MACHINES

The operating condition of a turbomachine will be *dynamically similar* at two different rotational speeds if all fluid velocities at *corresponding points* within the machine are in the same direction and proportional to the blade speed. In other words, the flow is dynamically similar if the streamline patterns relative to the blades are geometrically similar. When two flow-fields are dynamically similar then *all* the dimensionless groups are the same. As shown by eqns. (2.3), for an incompressible flow machine (one in which $M < 0.3$ everywhere) operating at high Reynolds number, dynamic similarity is achieved once the flow coefficient is the same. Thus, the non-dimensional presentation of performance data has the important practical advantage of collapsing results into a single curve that would otherwise require a multiplicity of curves if plotted dimensionally.

Evidence in support of the foregoing assertion is provided in Figure 2.2, which shows experimental results obtained by one author (at the University of Liverpool) on a simple centrifugal laboratory pump.

FIGURE 2.2

Dimensionless Head-Volume Characteristic of a Centrifugal Pump

**FIGURE 2.3**

Extrapolation of Characteristic Curves for Dynamically Similar Conditions at $N = 3500$ rpm

Within the normal operating range of this pump, $0.03 < Q/(ND^3) < 0.06$, very little systematic scatter is apparent, which might be associated with a Reynolds number effect, for the range of speeds $2500 \leq N \leq 5000$ rev/min. For smaller flows, $Q/(ND^3) < 0.025$, the flow became unsteady and the manometer readings of uncertain accuracy, but nevertheless, dynamically similar conditions still appear to hold true. Examining the results at high flow rates one is struck by a marked systematic deviation away from the “single-curve” law at increasing speed. This effect is due to *cavitation*, a high speed phenomenon of hydraulic machines caused by the release of vapour bubbles at low pressures, which is discussed later in this chapter. It will be clear at this stage that under cavitating flow conditions, dynamical similarity is not possible.

The non-dimensional results shown in Figure 2.2 have, of course, been obtained for a particular pump. They would also be approximately valid for a range of *different* pump sizes so long as all these pumps are geometrically similar and cavitation is absent. Thus, neglecting any change in performance due to change in Reynolds number, the dynamically similar results in Figure 2.2 can be applied to predicting the dimensional performance of a given pump for a series of required speeds. Figure 2.3 shows such a dimensional presentation. It will be clear from the preceding discussion that the locus of dynamically similar points in the H - Q field lies on a parabola since H varies as N^2 and Q varies as N .

2.4 COMPRESSIBLE FLUID ANALYSIS

The application of dimensional analysis to compressible flow increases, not unexpectedly, the complexity of the functional relationships obtained in comparison with those already found for incompressible fluids. Even if the fluid is regarded as a perfect gas, in addition to the previously used fluid

properties, two further characteristics are required; these are a_{01} , the stagnation speed of sound at entry to the machine, and γ , the ratio of specific heats C_p/C_v . In the following analysis the compressible fluids under discussion are either perfect gases or else dry vapours approximating in behaviour to a perfect gas.

Another choice of variables is preferred when appreciable density changes occur across the machine. Instead of volume flow rate Q , the mass flow rate \dot{m} is used; likewise for the head change H , the isentropic *stagnation enthalpy* change Δh_{0s} is employed. The choice of this last variable is a significant one for, in an ideal and adiabatic process, Δh_{0s} is equal to the work done per unit mass of fluid. Since heat transfer from the casings of turbomachines is, in general, of negligible magnitude compared with the flux of energy through the machine, temperature on its own may be safely excluded as a fluid variable. However, temperature is an easily observable characteristic and, for a perfect gas, can be easily introduced by means of the equation of state, $p/\rho = RT$.

The performance parameters Δh_{0s} , η , and P , for a turbomachine handling a compressible flow, can be expressed functionally as

$$\Delta h_{0s}, \eta, P = f(\mu, N, D, \dot{m}, \rho_{01}, a_{01}, \gamma). \quad (2.5)$$

Because ρ_0 and a_0 change through a turbomachine, the values of these fluid variables are selected at inlet, denoted by subscript 1. Equation (2.5) expresses *three* separate functional relationships, each of which consists of eight variables. Again, selecting ρ_{01} , N , and D as common factors, each of these three relationships may be reduced to five dimensionless groups:

$$\frac{\Delta h_{0s}}{N^2 D^2}, \eta, \frac{P}{\rho_{01} N^3 D^5} = f\left\{ \frac{\dot{m}}{\rho_{01} N D^3}, \frac{\rho_{01} N D^2}{\mu}, \frac{N D}{a_{01}}, \gamma \right\}. \quad (2.6a)$$

The group ND/a_{01} can be regarded as a *blade Mach number* because ND is proportional to blade speed. Since this appears as an independent variable on the right-hand side of the equation, it can be used to re-write the preceding relationships in terms of the inlet stagnation speed of sound a_{01} :

$$\frac{\Delta h_{0s}}{a_{01}^2}, \eta, \frac{P}{\rho_{01} a_{01}^3 D^2} = f\left\{ \frac{\dot{m}}{\rho_{01} a_{01} D^2}, \frac{\rho_{01} a_{01} D}{\mu}, \frac{N D}{a_{01}}, \gamma \right\}. \quad (2.6b)$$

For a machine handling a perfect gas a different set of functional relationships is often more useful. These may be found either by selecting the appropriate variables for a perfect gas and working through again from first principles or, by means of some rather straightforward transformations, rewriting eqn. (2.6b) to give more suitable groups. The latter procedure is preferred here as it provides a useful exercise. As an example consider an adiabatic compressor handling a perfect gas. The isentropic stagnation enthalpy rise can be written as $C_p(T_{02s} - T_{01})$ for a perfect gas. As shown in Chapter 1, the isentropic relationship between temperature and pressure is given by

$$\frac{T_{02s}}{T_{01}} = \left(\frac{p_{02}}{p_{01}} \right)^{(\gamma-1)/\gamma}.$$

The isentropic stagnation enthalpy rise can therefore be written as

$$\Delta h_{0s} = C_p T_{01} [(p_{02}/p_{01})^{(\gamma-1)/\gamma} - 1]. \quad (2.7)$$

Since $C_p = \gamma R / (\gamma - 1)$ and $a_{01}^2 = \gamma R T_{01}$, then $a_{01}^2 = (\gamma - 1) C_p T_{01}$ and thus,

$$\frac{\Delta h_{0s}}{a_{01}^2} = \frac{\Delta h_{0s}}{(\gamma - 1) C_p T_{01}} = \frac{1}{(\gamma - 1)} \left[\left(\frac{p_{02}}{p_{01}} \right)^{(\gamma - 1)/\gamma} - 1 \right] = f(p_{02}/p_{01}, \gamma).$$

Using the equation of state, $p/\rho = RT$, the non-dimensional mass flow can be more conveniently expressed as

$$\hat{m} = \frac{\dot{m}}{\rho_{01} a_{01} D^2} = \frac{\dot{m} R T_{01}}{p_{01} \sqrt{\gamma R T_{01}} D^2} = \frac{\dot{m} \sqrt{\gamma R T_{01}}}{D^2 p_{01} \gamma}.$$

The power coefficient can also be re-written as

$$\hat{P} = \frac{P}{\rho_{01} a_{01}^3 D^2} = \frac{\dot{m} C_p \Delta T_0}{(\rho_{01} a_{01} D^2) a_{01}^2} = \hat{m} \frac{C_p \Delta T_0}{a_{01}^2} = \frac{\hat{m}}{(\gamma - 1)} \frac{\Delta T_0}{T_{01}}.$$

Collecting together these newly formed non-dimensional groups and inserting them in eqn. (2.6b) leads to a simpler and more useful functional relationship:

$$\frac{p_{02}}{p_{01}}, \eta, \frac{\Delta T_0}{T_{01}} = f \left\{ \frac{\dot{m} \sqrt{\gamma R T_{01}}}{D^2 p_{01}}, \frac{ND}{\sqrt{\gamma R T_{01}}}, \text{Re}, \gamma \right\}. \quad (2.8)$$

A key advantage of eqn. (2.8) over eqn. (2.6b) is that the non-dimensional groups are in terms of inlet and exit stagnation temperatures and pressures, which are parameters that are readily measured for a turbomachine. For a machine handling a single gas γ can be dropped as an independent variable. If, in addition, the machine operates only at high Reynolds numbers (or over a small speed range), Re can also be dropped. Equation (2.8) can then be written with just two non-dimensional groups on the right-hand side:

$$\frac{p_{02}}{p_{01}}, \eta, \frac{\Delta T_0}{T_{01}} = f \left\{ \frac{\dot{m} \sqrt{C_p T_{01}}}{D^2 p_{01}}, \frac{ND}{\sqrt{\gamma R T_{01}}} \right\}. \quad (2.9a)$$

In this equation, the non-dimensional group, $\dot{m} \sqrt{C_p T_{01}} / D^2 p_{01}$ is often referred to as the *flow capacity*, introduced in the compressible flow section of Chapter 1. This is the most widely used form of non-dimensional mass flow, although the forms in eqns. (2.6b) and (2.8) are also valid. For machines of a known size and fixed working fluid, it has become customary, in industry at least, to delete γ , R , C_p , and D from eqn. (2.9a) and similar expressions. Under these conditions eqn. (2.9a) becomes

$$\frac{p_{02}}{p_{01}}, \eta, \frac{\Delta T_0}{T_{01}} = f \left\{ \frac{\dot{m} \sqrt{T_{01}}}{p_{01}}, \frac{N}{\sqrt{T_{01}}} \right\}. \quad (2.9b)$$

Note that by omitting the diameter D and gas constant R , the independent variables in eqn. (2.9b) are no longer dimensionless.

Equations (2.9a) and (2.9b) show that two variables are required to fix the operating point of a compressible flow machine. This compares to the one variable needed to fix the operating point of

an incompressible flow machine, eqn. (2.3). In all cases, for dynamic similarity the streamline pattern relative to the blades must be geometrically similar. In an incompressible flow machine it is enough just to fix the relative inlet angle to the blades (via the flow coefficient). In a compressible flow machine, the streamline pattern within the blade rows also depends on the variation of density through the blade passages. Therefore a second parameter is needed to fix the flow Mach numbers and thus fix the variation of density.

Similarly to the incompressible case, the performance parameters, p_{02}/p_{01} , η , and $\Delta T_0/T_{01}$ are not entirely independent and it is straightforward to write an equation relating the three. For a compressor, the isentropic efficiency is defined in Chapter 1 and can be written as

$$\eta_c = \frac{\Delta h_{0s}}{\Delta h_0} = \frac{[(p_{02}/p_{01})^{\gamma/(\gamma-1)} - 1]}{\Delta T_0/T_{01}}. \quad (2.10)$$

Flow Coefficient and Stage Loading

In compressible flow machines, the flow coefficient, Φ , is an important parameter for design and analysis. It is defined in the same way as given earlier for incompressible machines, i.e., $\Phi = c_m/U$ where U is the mean blade speed and c_m the average meridional velocity. However, in the compressible case, the flow coefficient alone cannot be used to fix the operating condition of a machine. This is because the flow coefficient is also a function of the non-dimensional parameters given in eqn. (2.9a). This is straightforward to show via the following algebraic manipulation:

$$\Phi = \frac{c_m}{U} = \frac{\dot{m}}{\rho_{01} A_1 U} = \frac{\dot{m} R T_{01}}{p_{01} A_1 U} \propto \frac{\dot{m} \sqrt{C_p T_{01}}}{D^2 p_{01}} \times \frac{\sqrt{C_p T_{01}}}{U} = f \left\{ \frac{\dot{m} \sqrt{C_p T_{01}}}{D^2 p_{01}}, \frac{ND}{\sqrt{\gamma R T_{01}}} \right\}.$$

Note that the non-dimensional mass flow $\dot{m} \sqrt{C_p T_{01}}/D^2 p_{01}$ is distinct from a flow coefficient because it does not involve the blade speed.

The stage loading, ψ , is another key design parameter for non-hydraulic turbomachines. It is defined as

$$\psi = \frac{\Delta h_0}{U^2}. \quad (2.11)$$

This parameter is similar in form to the head coefficient ψ used in hydraulic machines (eqn. 2.2a), but there are subtle differences. Most importantly, stage loading is a non-dimensional form of the actual specific stagnation enthalpy change, whereas the head coefficient is a non-dimensional measure of the maximum, or isentropic, work that a hydraulic machine can achieve. Note that the stage loading can be related to the non-dimensional parameters in eqn. (2.9a) as follows:

$$\psi = \frac{\Delta h_0}{U^2} = \frac{C_p \Delta T_0}{C_p T_{01}} \frac{C_p T_{01}}{U^2} = \frac{\Delta T_0}{T_{01}} \left/ \left(\frac{U}{\sqrt{C_p T_{01}}} \right)^2 \right. = f \left\{ \frac{\dot{m} \sqrt{C_p T_{01}}}{D^2 p_{01}}, \frac{ND}{\sqrt{\gamma R T_{01}}} \right\}.$$

Thus, the stage loading is also fixed once both the non-dimensional mass flow and the non-dimensional blade speed (or blade Mach number) are fixed. In many cases, the stage loading is used in place of the power coefficient $\Delta T_0/T_0$ given in eqn. (2.9a).

2.5 PERFORMANCE CHARACTERISTICS FOR HIGH SPEED MACHINES

Compressors

The performance map of a high speed compressor is essentially a graphical representation of the functional relationship given in eqn. (2.9b). As shown in the example in Figure 2.4, the pressure ratio across the whole machine is plotted as a function of $\dot{m}\sqrt{T_{01}}/p_{01}$ for several fixed values of $N/\sqrt{T_{01}}$, this being a customary method of presentation. Figure 2.4 also shows contours of compressor efficiency on the same axes.

Each of the constant speed curves on the compressor characteristic terminate at the surge (or stall) line. Beyond this point the operation is unstable. A discussion of the phenomena of surge and stall is included in Chapter 5. At high speeds and low pressure ratios the constant speed curves become vertical. In these regions of the characteristic, no further increase in $\dot{m}\sqrt{T_{01}}/p_{01}$ is possible since the Mach number across a section of the machine has reached unity and the flow is said to be *choked*.

A compressor is able to operate anywhere below and to the right of the surge line. However, it is usually constrained to a single *operating line*, which is set by the flow area downstream of the compressor. The design operating line is often specified so that it passes through the point of peak compressor efficiency. However, its exact position is a matter of judgement for the compressor designer. The term *stall margin* is often used to describe the relative position of the operating

FIGURE 2.4

Overall Characteristic of a High Speed Compressor

line and the surge line. There are several ways of defining the surge margin (SM) and a fairly simple one often used is

$$SM = \frac{(pr)_s - (pr)_o}{(pr)_o}, \quad (2.12)$$

where $(pr)_o$ is a pressure ratio at a point on the operating line at a certain corrected speed $N/\sqrt{T_{01}}$ and $(pr)_s$ is the corresponding pressure ratio on the surge line at the same corrected speed. With this definition a surge margin of 20% would be typical for a compressor used within a turbojet engine. Several other definitions of *stall margin* and their merits are discussed by Cumpsty (1989).

Turbines

Figure 2.5 shows a typical high speed turbine characteristic. Turbine characteristics are plotted in the same way as compressor characteristics but the behaviour is very different. Turbines are able to operate with a high pressure ratio across each stage because the boundary layers on the surfaces of the turbine blades are accelerating and therefore stable. The high pressure ratios soon lead to choking in the turbine stator blades and therefore a fixed non-dimensional mass flow through the machine. Once the turbine stators are fully choked, the operating point is independent of $N/\sqrt{T_{01}}$ because the rotation of the blades has virtually no influence on either the turbine pressure ratio or the non-dimensional mass flow rate.

FIGURE 2.5

Overall Characteristic of a High Speed Turbine

Example 2.1

The compressor of a jet engine is tested at sea level on a stationary test bed on a day when the atmospheric temperature and pressure is 298 K and 101 kPa, respectively. When running at its design operating point, the mass flow rate through the compressor is measured as 15 kg/s and the rotational speed is 6200 rpm. Determine the mass flow rate and rotational speed when the compressor is operating at the design operating point during high altitude cruise with an inlet stagnation temperature of 236 K and an inlet stagnation pressure of 10.2 kPa.

The design pressure ratio of the compressor is 20. If the compressor isentropic efficiency is determined from the test to be 85%, calculate the power input at the cruise condition. Assume for air that $\gamma = 1.4$ and $C_p = 1005 \text{ J kg}^{-1} \text{ K}^{-1}$ throughout.

Solution

At cruise and during the test the compressor is operating at its design non-dimensional operating point. Therefore, all the non-dimensional performance parameters of the compressor will be the same at both conditions.

The non-dimensional mass flow is

$$\left[\frac{\dot{m} \sqrt{\gamma R T_{01}}}{D^2 p_{01}} \right]_{\text{cruise}} = \left[\frac{\dot{m} \sqrt{\gamma R T_{01}}}{D^2 p_{01}} \right]_{\text{test}}.$$

Since there is no change in the dimensions of the compressor or in the gas properties of the working fluid, this reduces to

$$\left[\frac{\dot{m} \sqrt{T_{01}}}{p_{01}} \right]_{\text{cruise}} = \left[\frac{\dot{m} \sqrt{T_{01}}}{p_{01}} \right]_{\text{test}}.$$

During the test, the compressor is stationary and therefore the inlet air stagnation temperature and pressure are equal to the atmospheric static temperature and pressure. The mass flow at cruise is thus,

$$\dot{m}_{\text{cruise}} = \left[\frac{p_{01}}{\sqrt{T_{01}}} \right]_{\text{cruise}} \times \left[\frac{\dot{m} \sqrt{T_{01}}}{p_{01}} \right]_{\text{test}} = \frac{10.2}{\sqrt{236}} \times \frac{15 \times \sqrt{298}}{101} = \underline{1.70 \text{ kg/s}}.$$

Similarly for the non-dimensional speed,

$$\left[\frac{N}{\sqrt{T_{01}}} \right]_{\text{cruise}} = \left[\frac{N}{\sqrt{T_{01}}} \right]_{\text{test}} \text{ and thus, } N_{\text{cruise}} = \sqrt{T_{01, \text{cruise}}} \times \left[\frac{N}{\sqrt{T_{01}}} \right]_{\text{test}} = \sqrt{236} \times \left[\frac{6200}{\sqrt{298}} \right] = \underline{5520 \text{ rpm}}.$$

The input power to the compressor at the cruise condition can be found using the fact that the non-dimensional power coefficient $\Delta T_0/T_0$ is unchanged between the two conditions. From eqn. (2.10),

$$\frac{\Delta T_0}{T_{01}} = \frac{\left((p_{02}/p_{01})^{\gamma/(\gamma-1)} - 1 \right)}{\eta_c} = \frac{20^{0.4/1.4} - 1}{0.85} = 1.592,$$

$$P_{\text{cruise}} = [\dot{m} C_p \Delta T_0]_{\text{cruise}} = [\dot{m} C_p T_{01}]_{\text{cruise}} \left[\frac{\Delta T_0}{T_{01}} \right] = 1.70 \times 1005 \times 236 \times 1.592 = \underline{642 \text{ kW}}.$$

2.6 SPECIFIC SPEED AND SPECIFIC DIAMETER

The turbomachine designer is often faced with the basic problem of deciding what type of machine will be the best choice for a given duty. At the outset of the design process some overall requirements of the machine will usually be known. For a hydraulic pump these would include the head required H , the volume flow rate Q , and the rotational speed N . In contrast, if a high speed gas turbine was being considered, the initial specification would probably cover the mass flow rate \dot{m} , the specific work Δh_0 , and the preferred rotational speed Ω .

Two non-dimensional parameters called the *specific speed*, N_s , and *specific diameter*, D_s , are often used to decide upon the choice of the most appropriate machine. The specific speed is derived from the non-dimensional groups defined in eqn. (2.3) in such a way that the characteristic diameter D of the turbomachine is eliminated. The value of N_s gives the designer a guide to the type of machine that will provide the normal requirement of high efficiency at the design condition. Similarly, the specific diameter is derived from these groups by eliminating the speed, N .

Consider a hydraulic turbomachine with fixed geometry. As shown by eqn. (2.3b) there will be a unique relationship between efficiency and flow coefficient if Reynolds number effects are negligible and cavitation absent. If the maximum efficiency $\eta = \eta_{\max}$, occurs at a unique value of flow coefficient $\Phi = \Phi_1$ and corresponding unique values of $\psi = \psi_1$ and $\hat{P} = \hat{P}_1$, it is possible to write

$$\frac{Q}{ND^3} = \Phi_1 = \text{constant}, \quad (2.13a)$$

$$\frac{gH}{N^2 D^2} = \psi_1 = \text{constant}, \quad (2.13b)$$

$$\frac{P}{\rho N^3 D^5} = \hat{P}_1 = \text{constant}. \quad (2.13c)$$

It is a simple matter to combine any pair of these expressions in such a way as to eliminate the diameter. For a pump the customary way of eliminating D is to divide $\Phi_1^{1/2}$ by $\psi_1^{3/4}$. Thus, at the operating point giving maximum efficiency,

$$N_s = \frac{\Phi_1^{1/2}}{\psi_1^{3/4}} = \frac{NQ^{1/2}}{(gH)^{3/4}}, \quad (2.14a)$$

where N_s is called the *specific speed*. The term *specific speed* is justified only to the extent that N_s is directly proportional to N . It is sometimes referred to as a *shape factor* since its value characterises the shape of the machine required.

In the case of a hydraulic turbine the *power specific speed* N_{sp} is often used and it is defined by

$$N_{sp} = \frac{\hat{P}_1^{1/2}}{\psi_1^{5/4}} = \frac{N(P/\rho)^{1/2}}{(gH)^{5/4}}. \quad (2.15a)$$

There is a simple connection between N_s and N_{sp} . By dividing eqn. (2.15a) by eqn. (2.14a) we obtain, for a hydraulic turbine,

$$\frac{N_{sp}}{N_s} = \frac{N(P/\rho)^{1/2} (gH)^{3/4}}{(gH)^{5/4} NQ^{1/2}} = \left(\frac{P}{\rho gQH} \right)^{1/2} = \sqrt{\eta}. \quad (2.16)$$

Similarly to specific speed, to form the *specific diameter*, any pair of expressions in eqn. (2.13) can be used to eliminate the speed, N . In the case of a pump we divide $\psi^{1/4}$ by $\Phi^{1/2}$. Thus,

$$D_s = \psi^{1/4} / \Phi^{1/2} = \frac{D(gH)^{1/4}}{Q^{1/2}}. \quad (2.17)$$

Equations (2.14a), (2.15a), and (2.17) are *dimensionless*. It is *always* safer and less confusing to calculate specific speed and specific diameter in one or another of these forms rather than dropping the factors g and ρ , which would make the equations *dimensional* and any values of specific speed or specific diameter obtained using them would then depend upon the choice of the units employed. The dimensionless forms of N_s (and N_{sp}) and D_s are the only ones used in this book. Another point arises from the fact that the rotational speed, N , is often expressed in the units of revolutions per unit of time so that, although N_s is dimensionless, numerical values of specific speed need to be thought of as revs. Alternative versions of eqns. (2.14a) and (2.15a) specified in radians are formed by simply replacing N with Ω in:

$$\Omega_s = \frac{\Omega Q^{1/2}}{(gH)^{3/4}}, \quad (2.14b)$$

$$\Omega_{sp} = \frac{\Omega \sqrt{P/\rho}}{(gH)^{5/4}}. \quad (2.15b)$$

The concept of specific speed just described is illustrated in Figure 2.6. This shows contours of Ω_s plotted as a function of flow coefficient Φ and head coefficient ψ using eqn. (2.14a). Also plotted on the same axes are typical characteristics of three types of hydraulic pumps. This plot demonstrates how for a given type of machine one value of N_s (or Ω_s) passes through the operating point of peak efficiency. In other words, once the specific speed is known, the machine type giving peak efficiency can be determined. Figure 2.6 also shows how low specific speed suits radial machines, since these tend to give a high pressure change to a low mass flow rate. In contrast, axial flow stages with widely spaced blades, are suited to high specific speed applications because they impart a small pressure change to a large mass flow rate.

Given that specific speed is defined at the point of maximum efficiency of a turbomachine, it becomes a parameter of great importance in selecting the type of machine required for a given duty. The maximum efficiency condition *replaces* the condition of geometric similarity, so that any alteration in specific speed implies that the machine design changes. Broadly speaking, each different class of machine has its optimum efficiency within its own fairly narrow range of specific speed. Figure 2.7 shows the ranges of specific speed appropriate to different types of turbomachine. Once the specific speed at the design condition is found, a well-designed machine selected using Figure 2.7, should give the maximum possible design efficiency.

**FIGURE 2.6**

Contours of Specific Speed Showing Characteristics of Various Pump Types

Example 2.2

- (a) A hydraulic turbine with a runner outside diameter of 4.31 m operates with an effective head H of 543 m at a volume flow rate of $71.5 \text{ m}^3/\text{s}$ and produces 350 MW of shaft power at a rotational speed of 333 rev/min. Determine, the specific speed, the specific diameter, and efficiency of this turbine.
- (b) Another geometrically and dynamically similar turbine with a runner 6.0 m diameter is to be built to operate with an effective head of 500 m. Determine the required flow rate, the expected power output, and the rotational speed of the turbine.

Solution

- (a) Note: All speeds are converted to rad/s; therefore $\Omega = 333 \times \pi/30 = 34.87 \text{ rad/s}$.

Using eqn. (2.14b), the specific speed is

$$\Omega_s = \Omega Q^{1/2} / (gH)^{3/4} = \frac{34.87 \times 71.5^{0.5}}{(9.81 \times 543)^{0.75}} = 0.473 \text{ rad}.$$

Using eqn. (2.17), the specific diameter is

$$D_s = \frac{D(gH)^{1/4}}{Q^{1/2}} = \frac{4.31 \times (9.81 \times 543)^{1/4}}{71.5^{1/2}} = 4.354.$$

For the turbine the net hydraulic power is

$$P_n = \rho g Q H = 9,810 \times 71.5 \times 543 = 380.9 \times 10^6 = 380.9 \text{ MW}.$$

**FIGURE 2.7**

Range of Specific Speeds for Various Types of Turbomachine (from Csanady, 1964)

The turbine efficiency is

$$\eta = 350/380.9 = 0.919.$$

(b) Transposing eqn. (2.17) we can find the volume flow rate:

$$Q = (D/D_s)^2 (gH)^{1/2} = (6/4.354)^2 (9.81 \times 500)^{1/2} = 133 \text{ m}^3/\text{s},$$

and the power output is

$$P = \eta \rho g Q H = 0.919 \times 9810 \times 133 \times 500 = 599.5 \text{ MW}.$$

We can determine the rotational speed from eqn. (2.14a) as

$$N = (30/\pi) \Omega_s (gH)^{3/4} / Q^{1/2} = 0.473 \times (9.81 \times 500)^{3/4} / 133^{1/2} = 229.6 \text{ rpm}.$$

It is possible that some adjustment to the speed would be needed to make it synchronous with the local electricity grid.

The Cordier Diagram

A rough but useful guide to the selection of the most appropriate type and size of compressor, pump or fan for a given duty and optimum efficiency is obtained by means of the Cordier diagram, Figure 2.8. Although the method was originally devised by Cordier (1953) further details are more readily accessed from the work of Csanady (1964) and, with some added elaboration, by Lewis (1996). Figure 2.8 shows, on the right-hand side, the recommended ranges for various types of turbomachines for which the method applies. It must be mentioned that the line presented is, in fact, a mean curve based upon results obtained from a large number of machines, so it represents a fairly broad spread of results on either side of the line. For many designs it would be possible to diverge from the line and still obtain high performance pumps, fans or compressors.

Following Lewis, an interesting and useful alternative presentation of the Cordier diagram can be made with ordinates Φ and ψ from the relationships already given. From eqns. (2.14a) and (2.17) we can derive the flow coefficient, Φ , and stage loading coefficient, ψ , as

$$\Phi = 1/(N_s D_s^3), \quad (2.18)$$

$$\psi = 1/(N_s^2 D_s^2). \quad (2.19)$$

FIGURE 2.8

Cordier Diagram for Machine Selection

**FIGURE 2.9**

Chart of ψ versus Φ for Various Pumps and Fans

By introducing the Cordier line data into these last two equations and replotting this information, a new and more definite shape of the optimum machine curves results, shown in Figure 2.9. The new curve is clearly divided into two main parts with centrifugal pumps operating at a fairly constant stage loading coefficient at roughly $\psi = 0.1$ over a flow coefficient range of $0.0001 \leq \Phi \leq 0.04$ and axial machines operating with a wide range of stage loading coefficients, $0.005 \leq \psi \leq 0.05$ and also a wide range of Φ . It is seen that mixed flow machines appear to be stuck in between in quite a narrow range of both ψ and Φ . One reason advanced for this apparently limited range is that designers would have a natural preference for *either* axial or centrifugal types as these have less manufacturing complexity than mixed flow machines. However, in some important high technological applications mixed flow machines have been the crucial choice. It was pointed out by Lewis that some applications, such as gas cooled nuclear reactors and hovercraft lift fans, which require a high mass flow at a high pressure ratio, are ideally suited for mixed flow fans rather than a single stage compressor.

Compressible Specific Speed

Specific speed has mostly been applied to the design and selection of low speed and hydraulic turbomachines. However, the notion of specific speed can equally be applied to a compressible flow

machine, and it is particularly useful for determining whether an axial or a radial flow machine is best for a particular requirement. As described in Baskharone (2006), for high speed machines the hydraulic machine definition is simply expressed in terms of parameters appropriate to compressible flow:

$$N_s = \frac{NQ^{1/2}}{(gH)^{3/4}} = N \left(\frac{\dot{m}}{\rho_e} \right)^{1/2} (\Delta h_{0s})^{-3/4}. \quad (2.20)$$

Note that in eqn. (2.20) the isentropic specific work Δh_{0s} is used rather than the actual specific work Δh_0 . In the case of a compressor this makes sense since the isentropic specific work can be determined from the required pressure ratio p_{02}/p_{01} using eqn. (2.7). The required pressure ratio is likely to be known at the outset of the design process, whereas the actual specific work input depends on the compressor efficiency, which in general will not be known. In the case of a turbine, the actual specific work is more likely to be a known requirement. In this case, efficiency can be estimated or the isentropic work approximated to be equal to the actual work required.

Equation (2.20) also requires the density of the working fluid at exit ρ_e . This can be estimated through knowledge of the expected conditions at exit from the machine. The extra uncertainty introduced by this is small and will usually have no effect on the preferred type of machine selected.

Example 2.3

An air turbine is required for a dentist's drill. For the drill bit to effectively abrade tooth enamel, the turbine must rotate at high speed, around 350,000 rpm. The turbine must also be very small so that it can be used to access all parts of a patient's mouth and an exit air flow rate in the region of 10 L/min is required for this. The turbine is to be driven by supply air at a pressure of 3 bar and a temperature of 300 K.

Calculate the specific speed of the turbine and use this to determine the type of machine required. Also estimate the power consumption of the turbine and account for how this power is used.

Solution

Putting the quantities into standard SI units,

$$\text{the rotational speed, } N = 300,000/60 = 5000 \text{ rev/s,}$$

$$\text{the exit volume flow rate, } \dot{m}/\rho_e = Q_e = 10/(1000 \times 60) = 0.000167 \text{ m}^3/\text{s}.$$

The isentropic specific work can be estimated assuming an isentropic expansion through the turbine. Treating air as a perfect gas with $\gamma = 1.4$ and $C_p = 1005 \text{ J kg}^{-1} \text{ K}^{-1}$,

$$\Delta h_{0s} = C_p T_{01} \left[1 - (p_{02}/p_{01})^{(\gamma-1)/\gamma} \right] = 1005 \times 300 \times \left[1 - \left(\frac{1}{3} \right)^{0.4/1.4} \right] = 81.29 \text{ kJ/kg}.$$

The specific speed can now be calculated from the information provided using eqn. (2.20):

$$N_s = \frac{NQ^{1/2}}{(gH)^{3/4}} = N \left(\frac{\dot{m}}{\rho_e} \right)^{1/2} (\Delta h_{0s})^{-3/4} = \frac{5000 \times 0.000167^{1/2}}{(81,290)^{3/4}} \cong 0.013 \text{ rev}$$

and

$$\Omega_s = N_s \times 2\pi \cong 0.084 \text{ rad.}$$

**FIGURE 2.10**

Pelton Wheel Turbine Impeller from a High Speed Dental Drill (from Sirona Dental)

Using the plot of machine type versus specific speed presented in Figure 2.7 it is immediately apparent that the only kind of turbine suitable for this very low specific speed is a Pelton wheel. In fact, all modern high speed dentist drills use Pelton wheels and a photograph of a typical impeller from one is shown in Figure 2.10.

The power used by the turbine can be approximated from the mass flow rate and the specific isentropic work output. Using a typical value for the exit air density this gives

$$P = \dot{m}\Delta h_{0s} = \rho_e Q_e \Delta h_{0s} \cong 1.16 \times 0.000167 \times 81,290 = \underline{15.7 \text{ W}}.$$

The majority of this power will be dissipated as heat through friction in the bearings, losses in the Pelton wheel, and friction with the tooth. This heat dissipation is the reason why an appreciable amount of cooling water is required for modern high speed dentist drills.

2.7 CAVITATION

Cavitation is the boiling of a liquid at normal temperature when the static pressure is made sufficiently low. It may occur at the entry to pumps or at the exit from hydraulic turbines in the vicinity of the moving blades. The dynamic action of the blades causes the static pressure to reduce locally in a region that is already normally below atmospheric pressure and cavitation can commence. The phenomenon is accentuated by the presence of dissolved gases that are released with a reduction in pressure.

For the purpose of illustration consider a centrifugal pump operating at constant speed and capacity. By steadily reducing the inlet pressure head a point is reached when streams of small vapour bubbles appear within the liquid and close to solid surfaces. This is called *cavitation inception* and commences in the regions of lowest pressure. These bubbles are swept into regions of higher pressure where they collapse. This condensation occurs suddenly, the liquid surrounding the bubbles either hitting the walls or adjacent liquid. The pressure wave produced by bubble collapse (with a magnitude on the order of 400 MPa) momentarily raises the pressure level in the vicinity and the action ceases. The cycle then

repeats itself and the frequency may be as high as 25 kHz (Shepherd, 1956). The repeated action of bubbles collapsing near solid surfaces leads to the well-known cavitation erosion.

The collapse of vapour cavities generates noise over a wide range of frequencies—up to 1 MHz has been measured (Pearsall, 1972), i.e., so-called white noise. Apparently the collapsing smaller bubbles cause the higher frequency noise and the larger cavities the lower frequency noise. Noise measurement can be used as a means of detecting cavitation (Pearsall, 1966; 1967). Pearsall and McNulty (1968) have shown experimentally that there is a relationship between cavitation noise levels and erosion damage on cylinders and conclude that a technique could be developed for predicting the occurrence of erosion.

Up to this point no detectable deterioration in performance occurs. However, with further reduction in inlet pressure, the bubbles increase both in size and number, coalescing into pockets of vapour that affects the whole field of flow. This growth of vapour cavities is usually accompanied by a sharp drop in pump performance as shown conclusively in Figure 2.2 (for the 5000 rev/min test data). It may seem surprising to learn that, with this large change in bubble size, the solid surfaces are much less likely to be damaged than at inception of cavitation. The avoidance of cavitation inception in conventionally designed machines can be regarded as one of the essential tasks of both pump and turbine designers. However, in certain recent specialised applications pumps have been designed to operate under *supercavitating* conditions. Under these conditions large size vapour bubbles are formed, but bubble collapse takes place *downstream* of the impeller blades. An example of the specialised application of a supercavitating pump is the fuel pumps of rocket engines for space vehicles where size and mass must be kept low at all costs. Pearsall (1966) has shown that the supercavitating principle is most suitable for axial flow pumps of high specific speed and has suggested a design technique using methods similar to those employed for conventional pumps.

Pearsall (1966) was one of the first to show that operating in the supercavitating regime was practicable for axial flow pumps, and he proposed a design technique to enable this mode of operation to be used. A detailed description was later published (Pearsall, 1973), and the cavitation performance was claimed to be much better than that of conventional pumps. Some further details are given in Chapter 7 of this book.

Cavitation Limits

In theory cavitation commences in a liquid when the static pressure is reduced to the vapour pressure corresponding to the liquid's temperature. However, in practice, the physical state of the liquid will determine the pressure at which cavitation starts (Pearsall, 1972). Dissolved gases come out of solution as the pressure is reduced, forming gas cavities at pressures in excess of the vapour pressure. Vapour cavitation requires the presence of nuclei—submicroscopic gas bubbles or solid non-wetted particles—in sufficient numbers. It is an interesting fact that in the absence of such nuclei a liquid can withstand negative pressures (i.e., *tensile stresses*)! Perhaps the earliest demonstration of this phenomenon was that performed by Osborne Reynolds (1882) before a learned society. He showed how a column of mercury more than twice the height of the barometer could be (and was) supported by the internal cohesion (stress) of the liquid. More recently Ryley (1980) devised a simple centrifugal apparatus for students to test the tensile strength of both plain, untreated tap water in comparison with water that had been filtered and then de-aerated by boiling. Young (1989) gives an extensive literature list covering many aspects of cavitation including the tensile strength of liquids. At room temperature the theoretical tensile strength of water is quoted as being as high as 1000 atm (100 MPa)! Special

pre-treatment (i.e., rigorous filtration and pre-pressurization) of the liquid is required to obtain this state. In general the liquids flowing through turbomachines will contain some dust and dissolved gases and under these conditions negative pressure does not arise.

A useful parameter is the available suction head at entry to a pump or at exit from a turbine. This is usually referred to as the *net positive suction head*, NPSH, defined as

$$H_s = (p_o - p_v)/(\rho g), \quad (2.21)$$

where p_o and p_v are the absolute stagnation and vapour pressures, respectively, at pump inlet or at turbine outlet.

To take into account the effects of cavitation, the performance laws of a hydraulic turbomachine should include the additional independent variable H_s . Ignoring the effects of Reynolds number, the performance laws of a constant geometry hydraulic turbomachine are then dependent on two groups of variable. Thus, the efficiency,

$$\eta = f(\Phi, N_{ss}), \quad (2.22)$$

where the *suction specific speed* $N_{ss} = NQ^{1/2}/(gH_s)^{3/4}$, determines the effect of cavitation, and $\Phi = Q/(ND^3)$, as before.

It is known from experiment that cavitation inception occurs for an almost constant value of N_{ss} for all pumps (and, separately, for all turbines) designed to resist cavitation. This is because the blade sections at the inlet to these pumps are broadly similar (likewise, the exit blade sections of turbines are similar) and the *shape* of the low pressure passages influences the onset of cavitation.

Using the alternative definition of suction specific speed $\Omega_{ss} = \Omega Q^{1/2}/(gH_s)^{1/2}$, where Ω is the rotational speed in rad/s, Q is the volume flow in m³/s, and gH_s is in m²/s², it has been shown empirically (Wislicenus, 1947) that

$$\Omega_{ss} \approx 3.0 \text{ (rad)} \quad (2.23a)$$

for pumps, and

$$\Omega_{ss} \approx 4.0 \text{ (rad)} \quad (2.23b)$$

for turbines.

Pearsall (1967) describes a supercavitating pump with a cavitation performance much better than that of conventional pumps. For this pump suction specific speeds Ω_{ss} up to 9.0 were readily obtained and, it was claimed, even better values might be possible but at the cost of reduced head and efficiency. It is likely that supercavitating pumps will be increasingly used in the search for higher speeds, smaller sizes, and lower costs.

PROBLEMS

1. A fan operating at 1750 rev/min at a volume flow rate of $4.25 \text{ m}^3/\text{s}$ develops a head of 153 mm measured on a water-filled U-tube manometer. It is required to build a larger, geometrically similar fan that will deliver the same head at the same efficiency as the existing fan but at a speed of 1440 rev/min. Calculate the volume flow rate of the larger fan.
2. An axial flow fan 1.83 m diameter is designed to run at a speed of 1400 rev/min with an average axial air velocity of 12.2 m/s. A quarter scale model has been built to obtain a check on the design and the rotational speed of the model fan is 4200 rev/min. Determine the axial air velocity of the model so that dynamical similarity with the full-scale fan is preserved. The effects of Reynolds number change may be neglected. A sufficiently large pressure vessel becomes available in which the complete model can be placed and tested under conditions of complete similarity. The viscosity of the air is independent of pressure and the temperature is maintained constant. At what pressure must the model be tested?
3. The water pump used to generate the plot shown in Figure 2.2 has an impeller diameter of 56 mm. When tested at a speed of 4500 rpm the head–volume flow rate characteristic produced can be approximated by the equation

$$H = 8.6 - 5.6 Q^2,$$

where H is in meters and Q in dm^3/s . Show that, provided viscous and cavitation effects are negligible, the characteristic of all geometrically similar pumps may be written in dimensionless form as

$$\psi = 4.78(1 - 1132\Phi^2),$$

where ψ is the dimensionless head coefficient, gH/N^2D^2 , and Φ is the flow coefficient, Q/ND^3 .

4. A water turbine is to be designed to produce 27 MW when running at 93.7 rev/min under a head of 16.5 m. A model turbine with an output of 37.5 kW is to be tested under dynamically similar conditions with a head of 4.9 m. Calculate the model speed and scale ratio. Assuming a model efficiency of 88%, estimate the volume flow rate through the model. It is estimated that the force on the thrust bearing of the full-size machine will be 7.0 GN. For what thrust must the model bearing be designed?
5. Derive the non-dimensional groups that are normally used in the testing of gas turbines and compressors. A compressor has been designed for normal atmospheric conditions (101.3 kPa and 15°C). To economise on the power required it is being tested with a throttle in the entry duct to reduce the entry pressure. The characteristic curve for its normal design speed of 4000 rev/min is being obtained on a day when the ambient temperature is 20°C. At what speed should the compressor be run? At the point on the characteristic curve at which the mass flow would normally be 58 kg/s the entry pressure is 55 kPa. Calculate the actual rate of mass flow during the test.
6. Describe, with the aid of sketches, the relationship between geometry and specific speed for pumps.
 - a. A model centrifugal pump with an impeller diameter of 20 cm is designed to rotate at 1450 rpm and to deliver 20 dm³/s of fresh water against a pressure of 150 kPa. Determine the specific speed and diameter of the pump. How much power is needed to drive the pump if its efficiency is 82%?
 - b. A prototype pump with an impeller diameter of 0.8 m is to be tested at 725 rpm under dynamically similar conditions as the model. Determine the head of water the pump must overcome, the volume flow rate, and the power needed to drive the pump.

Two-Dimensional Cascades

Let us first understand the facts and then we may seek the causes.

Aristotle

3.1 INTRODUCTION

The design and performance prediction of axial flow compressors and turbines has been based, in the main, upon measurements of the flow-through two-dimensional cascades of blades. However, to an increasing extent computational fluid dynamic (CFD) methods are now being used to simulate cascade testing. The flow within a turbomachine is, in general, unsteady and three dimensional. For cascade analysis, the flow across individual blade rows is treated as two dimensional and steady. This approach is appropriate for many compressor and turbine designs and the derived flow characteristics obtained from cascade tests have usually been found to be satisfactory, although laborious to collect.

Reviews of the many types of cascade tunnels, which includes low-speed, high-speed, intermittent blowdown, suction tunnels, etc. are available in the literature, e.g. Sieverding, (1985), Baines et al. (1982), and Hirsch (1993). The range of Mach numbers in axial flow turbomachines can be considered to extend from $M = 0.1$ to 2.5,

- (i) low speed, operating in the range 20–60 m/s;
- (ii) high speed, for the compressible flow range of testing.

A typical low speed, continuous running cascade tunnel is shown in Figure 3.1(a). This linear cascade of blades comprises a number of identical blades, equally spaced and parallel to one another. Figure 3.1(b) shows the test section of a cascade facility for transonic and moderate supersonic inlet velocities. The upper wall is slotted and equipped for suction, allowing operation in the transonic regime. The flexible section of the upper wall allows for a change of geometry so that a convergent–divergent nozzle can be formed, allowing the flow to expand to supersonic speeds upstream of the cascade.

It is most important that the flow across the central region of the cascade blades (where the flow measurements are made) is a good approximation to two-dimensional flow and that the flow repeats (i.e., is periodic) across several blade pitches. This effect could be achieved by employing a large number of long blades, but then an excessive amount of power would be required to operate the tunnel. With a tunnel of more compact size, aerodynamic difficulties become apparent and arise from the tunnel wall

**FIGURE 3.1**

Compressor Cascade Wind Tunnels: (a) Conventional Low Speed, Continuous Running Cascade Tunnel (Adapted from Carter, Andrews, and Shaw, 1950); (b) Transonic/Supersonic Cascade Tunnel (Adapted from Sieverding, 1985)

boundary layers interacting with the blades. In particular, and as illustrated in Figure 3.2(a), the tunnel wall boundary layer merges with the end blade boundary layer, and as a consequence, this blade usually stalls, resulting in a non-uniform flow across the cascade.

In a compressor cascade the rapid increase in pressure across the blades causes a marked thickening of the wall boundary layers and produces an effective contraction of the flow, as depicted in Figure 3.3. A *contraction coefficient*, used as a measure of the boundary layer growth through the cascade, is defined by $\rho_1 c_1 \cos \alpha_1 / (\rho_2 c_2 \cos \alpha_2)$. Carter, Andrews, and Shaw (1950) quoted values of 0.9 for a good tunnel dropping to 0.8 in normal high speed tunnels and even less in bad cases. These are values for compressor cascades; with turbine cascades higher values can be expected, since the flow is accelerating and therefore the boundary layers will not be thickened.

Because of the contraction of the main through-flow, the theoretical pressure rise across a compressor cascade, even allowing for losses, is never achieved. This will be evident since a contraction (in a subsonic flow) accelerates the fluid, which is in conflict with the diffuser action of the cascade.

To counteract these effects it is customary (in Great Britain) to use *at least* seven blades in a compressor cascade, each blade having a minimum aspect ratio (blade span–chord length) of 3. With seven blades, suction is desirable in a compressor cascade but it is not usual in a turbine cascade.

**FIGURE 3.2**

(a) Flow Entering Cascade without Boundary Layer Control Causes End Blade Stalling: (b) Application of Suction to Bottom Wall Boundary Layer Results in a More Uniform Flow without Blade Stall (Adapted from Carter et al., 1950)

**FIGURE 3.3**

Contraction of Streamlines Due to Boundary Layer Thickening (Adapted from Carter et al., 1950)

In the United States much lower aspect ratios are commonly employed in compressor cascade testing, the technique being the almost complete removal of tunnel wall boundary layers from all four walls using a combination of suction slots and perforated end walls to which suction is applied. Figure 3.2(b) illustrates the effective application of suction to produce a more uniform flow-field.

For axial flow machines of high hub-tip radius ratios, radial velocities are negligible and the flow may be described as two dimensional. The flow in the cascade is then likely to be a good model of the

flow in the machine. With lower hub–tip radius ratios, the blades of a turbomachine will normally have an appreciable amount of twist along their length and a varying *space–chord ratio*. In such cases a number of cascade test measurements can be applied to cover the design of the blade sections at a number of radial locations. However, it should be emphasized that, in all cases, the two-dimensional cascade is a simplified model of the flow within a turbomachine, which in reality can include various three-dimensional flow features. For sections of a turbomachine where there are separated flow regions, leakage flows or significant spanwise flows, the cascade model will not be accurate and careful consideration of the three-dimensional effects is required. Further details of three-dimensional flows in axial turbomachines are given in Chapter 6.

3.2 CASCADE GEOMETRY

A cascade blade profile can be conceived as a curved *camber line* upon which a *profile thickness distribution* is symmetrically superimposed. In Figure 3.4 two blades of a compressor cascade are shown together with the notation needed to describe the geometry. Several geometric parameters that characterise the cascade are

FIGURE 3.4

Compressor Cascade and Blade Notation

- (i) the *stagger angle*, ξ , the angle between the chord line and the reference direction;¹
- (ii) the *space-chord ratio*, s/l (in American practice the *solidity*, $\sigma = l/s$, is more frequently used);
- (iii) the *camber angle*, θ ;
- (iv) the *blade inlet angle*, α'_1 ;
- (v) the *blade outlet angle*, α'_2 .

Further parameters that are needed to describe the cascade blade shape include its camber line shape, thickness distribution, the radii at the leading and trailing edges, and the maximum thickness to chord ratio, t_{\max}/l .

The camber angle, θ , is the change in angle of the camber line between the leading and trailing edges that equals $\alpha'_1 - \alpha'_2$ in the notation of Figure 3.4. For circular arc camber lines the stagger angle is $\xi = \frac{1}{2}(\alpha'_1 + \alpha'_2)$. The change in angle of the flow is called the *deflection*, $\varepsilon = \alpha_1 - \alpha_2$, and in general this will be different to the camber angle due to flow incidence at the leading edge and deviation at the trailing edge. The incidence is the difference between the inlet flow angle and the blade inlet angle:

$$i = \alpha_1 - \alpha'_1. \quad (3.1)$$

The deviation is the difference between the exit flow angle and the blade exit angle:

$$\delta = \alpha_2 - \alpha'_2. \quad (3.2)$$

Compressor Blade Profiles

The modern approach in compressor design is to use blade profiles designed by the so-called prescribed velocity distribution (PVD) method. In this approach, the designer will select a blade surface velocity distribution and a computational method determines the aerofoil thickness and curvature variation required to achieve the desired aerodynamics. Despite this, many blade designs are still in use based upon geometrically prescribed profiles. The most commonly used geometric families are the American National Advisory Committee for Aeronautics (NACA) 65 Series, the British C Series, and the double circular arc (DCA) or biconvex blade.

The NACA 65 Series blades originated from the NACA aircraft wing aerofoil and were designed for approximately uniform loading. Figure 3.5 compares the profiles of the most widely used blade sections drawn at a maximum thickness to chord ratio of 20%, for the purpose of clarity. In fact the maximum t/c ratios of compressor blade sections are nowadays normally less than 10% and often a value of 5% is used because of the superior high Mach number performance than can be achieved with thinner blades. The NACA 65 Series has its maximum thickness at 40%, whereas the C Series is at 30% and the DCA Series is at 50%. These differences have a marked effect on the velocity distributions measured around the blades surfaces. Aerofoils with the maximum thickness near the leading edge and, consequently, with

¹Throughout the whole of this book all fluid and blade angles are measured from this reference direction, which is a line perpendicular to the cascade front (this is the axial direction, when the blades are in an annular arrangement).

**FIGURE 3.5**

Thickness Distributions for Various Compressor Blade Profiles

a well rounded leading edge have a wide operating range but a poorer high speed performance than blades with a sharp leading edge and the maximum thickness point further back.

The exact details of the different profiles are very well documented, e.g., Mellor (1956), Cumpsty (1989), Johnson and Bullock (1965), Aungier (2003), etc., and it is not thought useful or necessary to reproduce these in this book.

The actual blade shape is defined by one of these profile shapes superimposed on a camber line. This can be a simple circular arc although, according to Aungier (2003), a parabolic arc allows a more flexible style of blade loading. The blade profile is laid out with the selected scaled thickness distribution plotted normal to the chosen camber line. Correlations for the performance of the different styles of compressor aerofoil are discussed within section 3.5 on “Compressor cascade performance” later in this chapter.

Turbine Blade Profiles

The shape of turbine blades is less critical than it is in a compressor cascade. However, the designer still needs to exercise some care in the selection of blades to attain good efficiency with highly loaded blade rows. Nowadays, the process of blade row geometry (blade shape, flow angles, and space–chord ratio) is accomplished by computational methods but, ultimately, the designs still need to be backed up by cascade tests. Figure 3.6 shows a photograph of a typical high speed turbine cascade that is used to represent the aerofoils of a conventional low pressure turbine within an aero engine. The blade profiles illustrate the high turning and the contraction of the passage flow area within a turbine blade row.

During the early design phase of a turbine, or when cascade results are unavailable, one-dimensional calculations and correlation methods can be used to estimate the blade row performance of turbine blade rows. These are discussed within section 3.6 on “Turbine Cascades” later in this chapter.

**FIGURE 3.6**

A Cascade of High Speed Turbine Aerofoils (Courtesy of the Whittle Laboratory)

3.3 CASCADE FLOW CHARACTERISTICS

The fluid approaches the cascade from far upstream² with velocity c_1 at an angle α_1 and leaves far downstream of the cascade with velocity c_2 at an angle α_2 as shown in Figure 3.7. The aims of a cascade test are to measure the deviation angle, δ , and to characterise the losses generated within the flow as it passes through the blade passages.

Deviation arises through inviscid and viscous effects. The flow mechanisms are different for compressors and turbines and they will be described in detail later. Essentially though, the flow is unable to follow the blade angle precisely, such that it is *underturned* and thus leaves the trailing edge at a slightly different angle to the blade exit angle. Cascade losses arise from the growth of the boundary layers on the suction and pressure surfaces of the blades. These boundary layers combine at the blade trailing edge where they form the blade wake. As a result a local defect in stagnation pressure is created. As the flow moves downstream the wake widens, as shown in Figure 3.7, and becomes less intense. In addition, cascades operating at high Mach numbers have losses due to shock waves and shock–boundary layer interaction at the blade surfaces.

The deviation and loss for a cascade are measured (or computed) at a range of conditions, because as well as determining the design performance, it is important to check the tolerance to changes in the inlet flow conditions, i.e., to show good off-design behaviour. Note that cascade tests can be made on both rotor and stator blades. For rotors the absolute velocities in the cascade are equivalent to the relative velocities that would be present in the actual machine.

Streamtube Thickness Variation

When considering the flow through the blade passage of a compressor cascade it is often assumed that the mean streamtube thickness remains constant. However, this may not be true because the rapid increase in pressure of the flow through the blades can cause a marked thickening of the end wall

²Far upstream usually implies an indefinite distance of $\frac{1}{2}$ to 1 chord upstream of the leading edge at a location where the influence of the cascade static pressure field on the flow is negligible, similarly for far downstream.

**FIGURE 3.7**

The Flow through a Blade Cascade and the Formation of the Wakes (from Johnson and Bullock, 1965)

boundary layers resulting in an effective contraction of the flow as already indicated in Figure 3.3. This effect can be countered by the use of suction to remove the end wall boundary layers.

In general, for all flows, the conservation of mass flow rate per blade passage is

$$\dot{m} = \rho_1 c_1 H_1 s \cos \alpha_1 = \rho_2 c_2 H_2 s \cos \alpha_2, \quad (3.3)$$

where Hs is the projected frontal area of the control volume, A_a . The parameter $H_1 s \cos \alpha_1$ is the flow area measured *perpendicular to the inlet flow direction*. This is the area perceived by the flow and is therefore referred to as the *true flow area*. This is an important factor when compressible flow is considered.

It is useful to define an axial velocity density ratio (AVDR); i.e.,

$$\text{AVDR} = (\rho_2 c_{x2}) / (\rho_1 c_{x1}) = H_1 / H_2. \quad (3.4)$$

Equation (3.4) can be used in relating flow properties at the different positions along the mean stream-tube. Note that AVDR is the inverse of the contraction coefficient described in the introduction. In compressors $\text{AVDR} > 1$ due to the thickening boundary layers, but in turbine cascades AVDR may be less than 1 due to the possible thinning of the boundary layers in accelerating flow.

Cascade Performance Parameters

For a known AVDR, as just defined, the primary aerodynamic input data for a cascade test are

- (i) the inlet flow angle, α_1 ;
- (ii) the inlet Mach number, M_1 ;
- (iii) the blade Reynolds number, $Re = \rho_1 c_1 l / \mu$, where l is the blade chord.

The data from cascade traverses are used to provide the following parameters for use in the design and performance prediction of axial flow compressors and turbines:

- (i) Exit flow angle, α_2 ;
- (ii) Stagnation pressure loss, Y_p , or an energy loss coefficient, ζ .

The performance characteristics of a cascade of the cascade can therefore be expressed by the following functional relationships:

$$\alpha_2 = \text{fn}(M_1, \alpha_1, Re); Y_p = \text{fn}(M_1, \alpha_1, Re); \text{ or } \zeta = \text{fn}(M_1, \alpha_1, Re).$$

The exit flow angle, α_2 , is a critical performance parameter because it determines the work transfer within a turbomachinery stage. If we revisit the Euler work equation from Chapter 1, $\Delta h_0 = \Delta(Uc_\theta)$, it is clear that the work input or output from a turbomachine will depend on the exit flow angles since $c_\theta = c \sin \alpha$.

The *stagnation pressure loss coefficient* is an overall measure of the aerodynamic losses through the blade row. Generally, it is defined as

$$Y_p = \text{loss of stagnation pressure} \div \text{reference (dynamic) pressure}.$$

The aerodynamic losses in a cascade blade row translate into efficiency losses within a real turbomachine with the same blade shapes. The sources of losses can include

- (i) boundary layers on the blades;
- (ii) flow separation;
- (iii) shock waves in the flow.

If no shock waves are present most of the “loss” due to irreversibility is confined to a narrow wake downstream of the trailing edge as shown in Figure 3.7.

For *compressors*, the total pressure loss coefficient is based on *reference inlet conditions*, i.e.,

$$Y_p = (p_{01} - p_{02}) / (p_{01} - p_1). \quad (3.5)$$

A Mollier diagram with the pressures and salient points for a compressor blade cascade is shown in Figure 3.8(a).

For *turbines*, the total pressure loss coefficient is based on *reference exit conditions*, i.e.,

$$Y_P = (p_{01} - p_{02}) / (p_{01} - p_2). \quad (3.6)$$

In this case the reference dynamic pressure is the dynamic pressure at exit if the flow were isentropic. Other variations of the turbine loss coefficient are used in the literature and Horlock (1966) gives a comprehensive list of the definitions possible.

**FIGURE 3.8**

Mollier Diagrams for the Flow through (a) a Compressor Blade Cascade and (b) a Turbine Blade Cascade

An alternative loss parameter is sometimes used for turbines, called the *energy loss coefficient*, ζ , which measures the lost kinetic energy relative to the *isentropic* exit kinetic energy:

$$\zeta = (c_{2is}^2 - c_2^2) / c_{2is}^2, \text{ where } 0.5c_{2is}^2 = h_{01} - h_{2s}. \quad (3.7)$$

Figure 3.8(b) is a Mollier diagram³ indicating the pressures and enthalpies for the flow through a turbine cascade blade row.

The two definitions of loss coefficient yield numerical values that are almost identical at low Mach numbers but their values rapidly diverge as M_2 increases with $Y_p > \zeta$.

A primary objective of a compressor blade is to produce a rise in static pressure as well as a deflection of the flow angle. A relevant performance parameter is therefore the static pressure rise coefficient. For compressible flow this is usually defined as

$$C_p = (p_2 - p_1) / (p_{01} - p_1), \quad (3.8a)$$

and for incompressible flow

$$C_p = (p_2 - p_1) / \left(\frac{1}{2} \rho c_1^2 \right). \quad (3.8b)$$

Flow measurements are made usually across either one or two blade pitches of the varying values of stagnation and static pressures, p_{02} and p_2 , and the values of α_2 . Mass-averaged values of the performance parameters are then derived from these flow measurements. For example, the mass flow rate is given by

$$\dot{m} = \int_0^s \rho c H \cos \alpha dy = \int_0^s \rho c_x H dy. \quad (3.9)$$

³The enthalpy changes for the turbine and compressor cascades are drawn roughly equal only for expediency. In fact, the turbine enthalpy drop will be three or four times larger than the enthalpy rise in the compressor blade row.

FIGURE 3.9

Typical Traverse Results for a Compressor Cascade

A mean value of the air angle α_2 can be found from integrals of tangential and axial momentum across the pitch:

$$\tan \alpha_2 = \int_0^s \rho c_x c_y dy / \int_0^s \rho c_x^2 dy. \quad (3.10)$$

Finally, the mass-averaged stagnation pressure loss coefficient is

$$Y_p = \left\{ \int_0^s (p_{01} - p_{02}) / (p_{01} - p_1) \right\} \rho c_x dy / \int_0^s \rho c_x dy. \quad (3.11)$$

Figure 3.9 shows representative traverse results of Y_p and α_2 for a compressor cascade together with the mass-averaged values of these parameters. The odd-looking “kinks” in the plot of α_2 are caused by the variation in the gradient of p_{02} across the wake and the response of a yaw meter used in measuring flow direction. Further details of these effects are given in a paper by Dixon (1978).

Note: From this point onwards all parameters, e.g., α_2 , Y_p , are taken as having been mass-averaged according to the formulae just outlined.

Blade Surface Velocity Distributions

The details of the flow and velocity variations within the blade passages are not required to derive the cascade performance metrics. However, blade surface velocity (and pressure) distributions are used to show whether a blade achieves the velocity distributions intended in the design, and they are helpful for understanding the way a cascade blade performs. In particular, the velocity variation on the blade suction surface can give an indication of imminent flow separation, which would lead to reduced turning

and high loss. The relationship between surface velocity distribution and blade performance is discussed further in the sections on turbine and compressor cascade performance.

3.4 ANALYSIS OF CASCADE FORCES

Lift and drag coefficients are frequently referred to in the general literature and in many later parts of this book, especially with regard to low speed fans and wind turbines. However, with the advent of much higher blade speeds in compressors and turbines, the effects of compressibility have become complicated matters and their usage has almost vanished. Instead, it is now common practice just to use flow deflection and non-dimensional total pressure loss in calculating performance, as described previously. This section is included for completeness, but it should be remembered that the material is applicable only to low speed turbomachines.

Consider a portion of a compressor blade cascade, as shown in Figure 3.10. The forces X and Y exerted by a unit depth of blade upon the fluid are exactly equal and opposite to the forces exerted by the fluid upon the blade. A control surface is drawn with end boundaries far upstream and downstream of the cascade and with side boundaries coinciding with the median stream lines.

The momentum equation is applied in the x and y directions assuming constant axial velocity, c_x gives the force components:

$$X = (p_2 - p_1)s, \quad (3.12)$$

$$Y = \rho s c_x (c_{y1} - c_{y2}) \quad (3.13a)$$

and

$$Y = \rho s c_x^2 (\tan \alpha_1 - \tan \alpha_2). \quad (3.13b)$$

FIGURE 3.10

Forces and Velocities in a Compressor Blade Cascade

Equations (3.12) and (3.13) are valid only for incompressible flow with total pressure losses in the cascade but with no change in axial velocity.

Lift and Drag Forces

A mean velocity c_m is defined by

$$c_m = c_x / \cos \alpha_m, \quad (3.14)$$

where α_m is itself defined by

$$\tan \alpha_m = \frac{1}{2} (\tan \alpha_1 + \tan \alpha_2). \quad (3.15)$$

Considering unit depth of a cascade blade, a lift force L acts in a direction perpendicular to c_m and a drag force D in a direction parallel to c_m . Figure 3.11 shows L and D as the reaction forces exerted by the blade upon the fluid.

Experimental data are often presented in terms of lift and drag when, in fact, the data could be of more use in the form of tangential force and total pressure loss. The lift and drag forces will now be resolved in terms of the axial and tangential forces. Referring to Figure 3.12,

$$L = X \sin \alpha_m + Y \cos \alpha_m, \quad (3.16)$$

$$D = Y \sin \alpha_m - X \cos \alpha_m. \quad (3.17)$$

There is an immediate connection between the drag force D and the mass-averaged stagnation pressure loss coefficient, Y_p . If we consider a unit blade length, the *force deficit* acting over the span as a result of the total pressure losses is $s\Delta p_0$, where $\Delta p_0 = p_{01} - p_{02}$ for the cascade. The drag is the force component shown in Figure 3.12, which is

$$D = s\Delta p_0 \cos \alpha_m. \quad (3.18)$$

This is a result of fundamental importance, but it is strictly only applicable to incompressible flows.

Clearly, the drag force $D = 0$ when $\Delta p_0 = 0$. From eqn. (3.17) with eqn. (3.18), the drag force is

$$D = \cos \alpha_m (Y \tan \alpha_m - X) = s\Delta p_0 \cos \alpha_m. \quad (3.19)$$

FIGURE 3.11

Lift and Drag Forces Exerted by a Unit Span of a Cascade Blade upon the Fluid

**FIGURE 3.12**

Axial and Tangential Forces Exerted by Unit Span of a Blade upon the Fluid

Rearranging the above equation we obtain X ,

$$X = Y \tan \alpha_m - s \Delta p_0. \quad (3.20)$$

Substituting eqn. (3.20) into eqn. (3.16) we find:

$$L = \sin \alpha_m (Y \tan \alpha_m - s \Delta p_0) + Y \cos \alpha_m = Y \sec \alpha_m - s \Delta p_0 \sin \alpha_m. \quad (3.21)$$

Substituting for Y using eqn. (3.13b), the lift becomes

$$L = \rho s c_x^2 (\tan \alpha_1 - \tan \alpha_2) \sec \alpha_m - s \Delta p_0 \sin \alpha_m. \quad (3.22)$$

Lift and Drag Coefficients

These coefficients are normally defined in terms of *incompressible flow* parameters. The lift coefficient is conventionally defined as

$$C_L = L / \left(\frac{1}{2} \rho c_m^2 l \right), \quad (3.23)$$

where $c_m = c_x / \cos \alpha_m$ = blade chord. The drag coefficient, similarly, is defined as

$$C_D = D / \left(\frac{1}{2} \rho c_m^2 l \right). \quad (3.24a)$$

Using the following incompressible definition of stagnation pressure loss coefficient,

$$\zeta = \Delta p_0 / \left(\frac{1}{2} \rho c_m^2 \right), \quad (3.24b)$$

and substituting for D with eqn. (3.18) then using eqn. (3.24b), we find

$$C_D = \frac{s\Delta p_0 \cos \alpha_2}{1/2 \rho c_m^2 l} = \frac{s\zeta 1/2 \rho c_m^2 \cos \alpha_2}{1/2 \rho c_m^2 l} = \frac{s}{l} \zeta \cos \alpha_2. \quad (3.25)$$

Again, we can write C_L in a more convenient form. From eqn. (3.22),

$$C_L = [\rho s c_x^2 (\tan \alpha_1 - \tan \alpha_2) \sec \alpha_m - s \Delta p_0 \sin \alpha_m] / \left(\frac{1}{2} \rho c_m^2 l \right).$$

Therefore

$$C_L = 2 \frac{s}{l} \cos \alpha_m (\tan \alpha_1 - \tan \alpha_2) - C_D \tan \alpha_m. \quad (3.26a)$$

Within the normal range of operation of the flow through a cascade, values of C_D are very much less than those of C_L . Thus, the approximation is occasionally found to be useful, i.e.,

$$\frac{L}{D} = \frac{C_L}{C_D} = \frac{2 \sec^2 \alpha_m}{\zeta} (\tan \alpha_1 - \tan \alpha_2). \quad (3.26b)$$

Circulation and Lift

Note: The classical analysis of the lift developed by a single isolated aerofoil is based upon the ideal case, when $D=0$, and the flow is incompressible, i.e., ρ is constant.

The *Kutta–Joukowski theorem* states that the lift force L is

$$L = \Gamma \rho c, \quad (3.27)$$

where c is the relative velocity between the aerofoil and the fluid at infinity and Γ is the circulation about the aerofoil. This theorem is of fundamental importance in the development of the theory of aerofoils (Glauert, 1959).

With the assumption that stagnation pressure losses are absent, the lift force per unit span of a blade *in cascade*, using eqn. (3.22), becomes

$$L = \rho s c_x^2 (\tan \alpha_1 - \tan \alpha_2) \sec \alpha_m = \rho s c_m (c_{y1} - c_{y2}). \quad (3.28)$$

Now the *circulation* is the contour integral of velocity around a closed curve. For the cascade blade the circulation is

$$\Gamma = s(c_{y1} - c_{y2}). \quad (3.29)$$

Combining eqns. (3.28) and (3.29),

$$L = \Gamma \rho c_m. \quad (3.30)$$

As the spacing between the cascade blades is increased without limit (i.e., $s \rightarrow \infty$), the inlet and outlet velocities to the cascade, c_1 and c_2 , becomes equal in magnitude and direction. Thus, $c_1 = c_2 = c_m$ and eqn. (3.30) becomes the same as the theorem of Kutta–Joukowski stated previously for an isolated aerofoil.

3.5 COMPRESSOR CASCADE PERFORMANCE

Within compressor blades, the flow is moving from a low static pressure at inlet towards a higher static pressure at exit. The fundamental difficulty in compressors is getting the flow to negotiate this pressure rise without generating high loss or separating. The axial compressor designer must choose an appropriate level of blade loading, such that the flow can achieve the required pressure rise, whilst not over-designing the compressor, such that there are too many blades. In addition, compressor blades are required to turn the flow. The designer needs to choose a blade geometry that can achieve the correct turning over a range of operating conditions.

This section describes the key phenomena present in compressor cascades that determine their overall performance. It also presents some research into the performance of compressors and the correlations that these past studies have established.

Compressor Loss and Blade Loading

Many experimental investigations have confirmed that the efficient performance of compressor cascade blades is limited by the growth and separation of the blade surface boundary layers. One of the aims of cascade research is to establish the generalised loss characteristics and stall limits of conventional blades. This task is made difficult because of the large number of factors that can influence the growth of the blade surface boundary layers, viz. surface velocity distribution, blade Reynolds number, inlet Mach number, free-stream turbulence and unsteadiness, and surface roughness. From the analysis of experimental data several correlation methods have been evolved that enable the first-order behaviour of the blade losses and limiting fluid deflection to be predicted with sufficient accuracy for engineering purposes.

The correlations of Lieblein (1959) and Johnson and Bullock (1965), are based on his observations that a large amount of velocity diffusion on compressor blade surfaces tends to produce thick boundary layers and eventual flow separation. Lieblein showed that in the region of minimum loss, the wake thickness and consequently the loss in total pressure are related to the diffusion in velocity on the suction surface of the blade in that region. He reasoned that the boundary layer on the *suction surface* of conventional compressor blades contributes the largest share of the blade wake, and, therefore, the suction-surface velocity distribution becomes the main factor in determining the total pressure loss.

A typical velocity distribution is shown in Figure 3.13 derived from surface pressure measurements on a compressor cascade blade operating in the region of minimum loss. From this it is clear that the fall in velocity on the suction surface is high and much greater the overall change, i.e., $c_{\max,s} - c_2 \gg c_1 - c_2$. Lieblein defined a term to quantify this diffusion on the suction surface, which he called the *local diffusion factor*,

$$DF_{\text{loc}} = (c_{\max,s} - c_2) / c_{\max,s}. \quad (3.31)$$

Since the local diffusion factor was relatively hard to determine, Lieblein, Schwenk, and Broderick (1953) developed the much used *diffusion factor* (DF) based on a theoretical surface velocity distribution similar to those actually measured on the NACA 65 Series and the British C4 Series cascades. This

FIGURE 3.13

Typical Velocity Distribution on a Compressor Cascade Blade (at or near Minimum Loss Condition)

parameter requires knowledge of only the inlet and exit velocities from the blade and the pitch–chord ratio and is therefore very useful for preliminary design purposes:

$$DF = (1 - c_2/c_1) + \left(\frac{c_{\theta 1} - c_{\theta 2}}{2c_1} \right) \frac{s}{l}. \quad (3.32)$$

The first term on the right-hand-side, $1 - c_2/c_1$, represents the mean deceleration of the flow. The second term, $(c_{\theta 1} - c_{\theta 2})/2c_1$, represents the flow turning. The pitch–chord ratio is important as this determines how well the flow is guided by the blades. A low value implies lower pressure gradients across the blade passages required to turn the flow and, hence, less diffusion. Lieblein showed that the loss in a blade row increases rapidly as the flow starts to separate when the diffusion factor exceeds 0.6. Typically, a well-designed blade with moderate loading will operate with a diffusion factor around 0.45. Although it was developed using just a small range of compressor blade designs operating at a minimum loss condition, the diffusion factor is widely applied to a range of compressor designs, both compressible and incompressible, for preliminary design purposes. For constant axial velocity and incompressible flow the diffusion factor can be written as

$$DF = \left(1 - \frac{\cos \alpha_1}{\cos \alpha_2} \right) + \frac{s \cos \alpha_1}{l} \frac{1}{2} (\tan \alpha_1 - \tan \alpha_2). \quad (3.33)$$

Thus, once the flow angles are fixed, a required level of diffusion factor can be used to set the pitch–chord ratio.

Lieblein (1960) also introduced a diffusion ratio expressed as the ratio of *maximum suction-surface velocity* to outlet velocity, $c_{\max,s}/c_2$. Lieblein found a correlation between the diffusion ratio $c_{\max,s}/c_2$ and the wake momentum thickness to chord ratio, θ_2/l , at the reference incidence (mid-point of working

**FIGURE 3.14**

Blade Wake Downstream of the Exit of a Compressor Blade Cascade

range) for American NACA 65-(A₁₀) and British C4 circular arc blades. For incompressible flow, the wake momentum thickness, with the parameters of the flow model in Figure 3.14 is defined as

$$\theta_2 = \int_{-s/2}^{s/2} (c/c_{\max})(1 - c/c_{\max}) dy. \quad (3.34)$$

Figure 3.14 shows the full blade wake in the exit plane of the cascade. Using Newton's second law of motion, we now equate the total loss in momentum due to friction with the drag force. This, of course, includes the boundary layers on both blade surfaces. Using eqn. (3.18), we get

$$D = s\Delta p_0 \cos \alpha_2 = \theta_2 \rho c_2^2, \quad (3.35)$$

where $\theta_2 = \theta_s + \theta_p$, i.e., the sum of the momentum thicknesses on the pressure and suction surfaces at the trailing edge plane.

From the definition of drag coefficient, eqn. (3.24a) and eqn.(3.35) it can be shown that

$$C_D = \zeta(s/l) \cos \alpha_2 = 2(\theta_2/l) \cos^2 \alpha_m / \cos^2 \alpha_2. \quad (3.36)$$

This equation provides a useful link between the drag coefficient and the wake momentum thickness.

The Lieblein correlation of momentum thickness to chord ratio is plotted against the diffusion ratio, $c_{\max,s}/c_2$, with the data points removed for clarity, is shown in Figure 3.15. This curve represents the equation

$$\frac{\theta_2}{l} = 0.004 / \left[1 - 1.17 \ln \left(\frac{c_{\max,s}}{c_2} \right) \right]. \quad (3.37)$$

It will be noticed that for the limiting case, $(\theta_2/l) \rightarrow \infty$, the corresponding upper limit for the diffusion ratio $c_{\max,s}/c_2$ is 2.35. The *practical limit of efficient operation* corresponds to a diffusion ratio of between 1.9 and 2.0.

The diffusion ratio requires a knowledge of suction-surface velocities. As these data may be unavailable an alternative method was developed using an *equivalent diffusion ratio*, DR_{eq} ,

FIGURE 3.15

Mean Variation of Wake Momentum Thickness–Chord Ratio with Suction-Surface Diffusion Ratio at Reference Incidence Condition for NACA 65-(C10A10)10 Blades and British C.4 Circular-Arc Blades (Adapted from Lieblein, 1959)

approximately equal to $c_{\max,s}/c_2$, which can be easily calculated from the inlet and outlet conditions of the cascade. First of all, an empirical correlation was established by Lieblein (1959) between a circulation parameter defined by

$$f(\Gamma) = \Gamma \cos \alpha_1 / (lc_1) \quad \text{and} \quad c_{\max,s}/c_1 \quad (3.38)$$

at the reference incidence, where the *ideal circulation*, $\Gamma = s(c_{y1} - c_{y2})$, is obtained from eqn. (3.29). The correlation then is simply the *linear* relation

$$c_{\max,s}/c_1 = 1.12 + 0.61f(\Gamma), \quad (3.39)$$

which applies to both NACA 65-(A₁₀) and C4 circular arc blades. Hence, the equivalent diffusion ratio, after substituting for Γ and simplifying, is

$$DR_{\text{eq}} = \frac{c_{\max,s}}{c_2} = \frac{\cos \alpha_2}{\cos \alpha_1} \left[1.12 + 0.61 \left(\frac{s}{l} \right) \cos^2 \alpha_1 (\tan \alpha_1 - \tan \alpha_2) \right]. \quad (3.40)$$

At incidence angles greater than reference incidence, Lieblein found that the following correlation was adequate:

$$DR_{\text{eq}} = \frac{\cos \alpha_2}{\cos \alpha_1} \left[1.12 + k(i - i_{\text{ref}})^{1.43} + 0.61 \left(\frac{s}{l} \right) \cos^2 \alpha_1 (\tan \alpha_1 - \tan \alpha_2) \right]. \quad (3.41)$$

Note: The reference incidence was loosely defined as the mid-point of the working range.

Example 3.1

A low speed compressor cascade is to be tested with a flow inlet angle, $\alpha_1 = 55^\circ$, and a flow exit angle, $\alpha_2 = 30^\circ$. The expected design value of the diffusion ratio, $c_{\max,s}/c_2$, is to be 1.95. Using the preceding equations, determine values for C_D and C_L . Also find a safe value for the pitch–chord ratio if the maximum value of the diffusion factor is assumed to be 0.6.

Solution

From eqn. (3.37), $\theta_2/l = 0.004/[1 - 1.17 \ln(1.95)] = 0.0183$.

From eqn. (3.36), $C_D = 2(\theta_2/l)\cos^2\alpha_m/\cos^2\alpha_2$, where $\tan\alpha_m = \frac{1}{2}(\tan\alpha_1 + \tan\alpha_2) = 1.00275$; therefore, $\alpha_m = 45.08^\circ$. Therefore,

$$C_D = 2 \times 0.0183 \times \cos^2 45.08 / \cos^2 30 = 0.02433.$$

From eqn. (3.26a), $C_L = 2s/l \cos\alpha_m(\tan\alpha_1 - \tan\alpha_2) - C_D \tan\alpha_m$; therefore,

$$C_L = 2 \times 1.075 \times \cos 45.08 \times (\tan 55 - \tan 30) - 0.2433 \times \tan 45.08 = 1.048.$$

Using eqn. (3.33) with the diffusion factor set at 0.6, the maximum allowable pitch–chord ratio is

$$\frac{s}{l} \leq \frac{2 \cos\alpha_1/\cos\alpha_2 - 0.8}{\cos\alpha_1(\tan\alpha_1 - \tan\alpha_2)} = \frac{2 \times 0.5736/0.866 - 0.8}{0.5736 \times (1.4281 - 0.5774)} = 1.075.$$

Nominal Deflection

In the early history of gas turbine development Howell (1942: 1945a: 1945b), Constant (1945), and others developed a simple approach for determining the stall limits of compressor cascade blades. Howell defined a *nominal fluid deflection* $\varepsilon^* = \alpha_1 - \alpha_2$ that corresponded to 80% of the stalling (or maximum) deflection of the flow through the cascade. The nominal deflections of the flow are, primarily, a function of the space–chord ratio s/l , the nominal fluid outlet angle α_2^* , and the Reynolds number Re , i.e.,

$$\varepsilon^* = f(s/l, \alpha_2^*, Re). \quad (3.42)$$

It is important to note that the correlation (which is really a correlation of stalling deflection, $\varepsilon_s = 1.25\varepsilon^*$) is virtually independent of blade camber θ in the normal range of choice of this parameter ($20^\circ < \theta < 40^\circ$). Figure 3.16 shows the variation of ε^* against α_2^* for several space–chord ratios. The dependence on Reynolds number based on blade chord is small for $Re > 3 \times 10^5$.

Fluid Deviation

The flow leaving a compressor blade does not follow the blade camber line at the trailing edge. This deviation arises partly because the flow is diffusing within the blade passages. This means that the streamlines are diverging and therefore the flow is not moving in a single direction. This effect is exacerbated by the spacing of the blades because the flow is guided less by the blades when they are further apart. The deviation is further increased by viscous effects since any boundary layer growth on the blade surfaces will generate a blockage that modifies the effective blade shape.

FIGURE 3.16

Variation of Nominal Deflection with Nominal Outlet Angle for Several Space–Chord Ratios for a Low Speed Compressor Cascade (Adapted from Howell, 1945a; 1945b)

Howell derived an empirical rule to relate the nominal deviation δ^* occurring at the nominal incidence angle i^* with the blade geometry:

$$\delta^* = m\theta(s/l)^n, \quad (3.43)$$

where $n \approx 0.5$ for compressor cascades and $n \approx 1$ for compressor *inlet guide vanes* (these are actually turbine blades as they accelerate the flow). The value of m depends upon the shape of the camber line and the blade setting. Howell's rule demonstrates that the deviation is found to increase with pitch–chord ratio and blade camber. For a compressor cascade,

$$m = 0.23(2a/l)^2 + \alpha_2^*/500, \quad (3.44)$$

where the maximum camber of the blade is at distance a from the leading edge.

Example 3.2

A compressor cascade has a space–chord ratio of unity and blade inlet and outlet angles of 50° and 20° , respectively. If the blade camber line is a circular arc (i.e., $a/l = 50\%$) and the cascade is designed to operate at the Howell nominal condition. Determine the fluid deflection, incidence, and ideal lift coefficient at the design point.

Solution

The camber, $\theta = \alpha_1' - \alpha_2' = 30^\circ$. As a first approximation put $\alpha_2^* = 20^\circ$ in eqn. (3.44) to give $m = 0.27$ and, using eqn. (3.43), $\delta^* = 0.27 \times 30 = 8.1^\circ$. As a better approximation put $\alpha_2^* = 28.1^\circ$ in eqn. (3.44) giving $m = 0.2862$ and $\delta^* = 8.6^\circ$. Thus, $\alpha_2^* = 28.6^\circ$ is sufficiently accurate.

From Figure 3.16 with $s/l = 1.0$ and $\alpha_2^* = 28.6^\circ$, find the value $\epsilon^* = \alpha_1^* - \alpha_2^* = 21^\circ$. Hence, $\alpha_1^* = 49.6^\circ$ and the nominal incidence is, therefore, $i^* = \alpha_1^* - \alpha_1' = -0.4^\circ$.

The *ideal* lift coefficient is found by setting $C_D = 0$ in eqn. (3.26a),

$$C_L = 2(s/l) \cos \alpha_m (\tan \alpha_1 - \tan \alpha_2).$$

Putting $\alpha_1 = \alpha_1^*$ and $\alpha_2 = \alpha_2^*$ and noting that $\tan \alpha_m = \frac{1}{2}(\tan \alpha_1^* + \tan \alpha_2^*)$ we obtain $\alpha_m^* = 40.75^\circ$; therefore,

$$C_L^* = 2(1.172 - 0.545) \times 0.758 \approx 0.95.$$

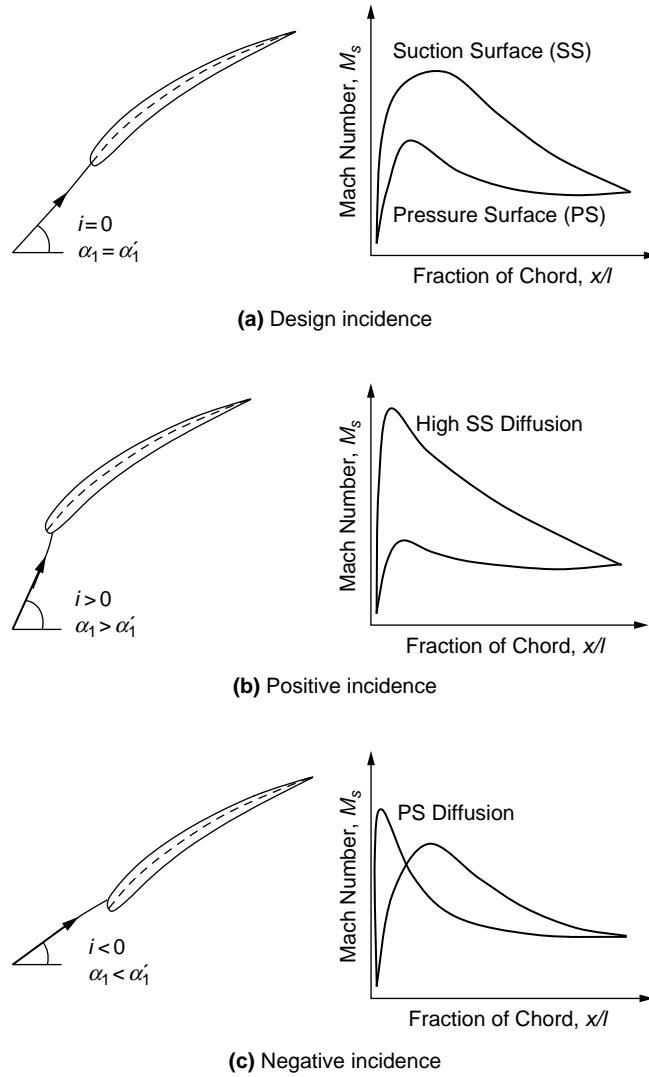

Incidence Effects

Figure 3.17 shows a schematic of the flow around a compressor blade for different incidence conditions as well as the corresponding surface pressure distributions for a compressor cascade. At the design point of a compressor blade the inlet flow angle is almost parallel to the camber line at the leading edge (i.e., the inlet blade angle). Hence, there is close to zero incidence and the surface pressure distribution for the blade should be smooth and continuous. In this case any deflection, or turning, of the flow is achieved via the camber of the blades. As the incidence is increased, the flow impinges on the blade pressure surface, and the flow on the suction surface must rapidly accelerate around the leading edge then decelerate to a speed comparable with the mainstream flow. This leads to very high local diffusion close to the front of the blade and sometimes what is referred to as a *leading edge spike* on the blade suction surface. The diffusion can cause boundary layer transition and, thus, higher blade losses, and at very high incidences the flow will separate, leading to stall. With positive incidence, the blade loading is higher and the flow deflection increased. Some of the turning can be thought of as being due to the blade camber, and some due to the incidence. At negative incidence, the flow accelerates around the leading edge onto the pressure surface. The pressure distributions on the front of the suction and pressure surfaces swap and the diffusion on the pressure surface is increased. The flow deflection is reduced and the loading is low. At very high values of negative incidence, the diffusion becomes so high that the flow can separate.

The tolerance of the compressor blades to incidence variations is critical to enable stable and efficient off-design operation of a compressor. When a compressor operates at mass flow rates or rotational speeds that are away from the design point, the blades will be subject to incidence variations, as detailed in Chapter 5. Typically, a compressor blade needs to tolerate at least $\pm 5^\circ$ variation of incidence without stalling, although the exact requirements will depend on the application. As shown later, the variations in incidence that can be tolerated by a compressor aerofoil reduce as the inlet Mach number increases.

Blade Inlet Mach Number

The peak Mach number on the surface of a conventional compressor blade is significantly higher than the inlet Mach number. Once the inlet Mach number exceeds about 0.7, the flow on the blade will become transonic, leading to performance deterioration. Figure 3.18 shows the surface Mach number

**FIGURE 3.17**

Effect of Incidence on the Surface Mach Number Distributions Around a Compressor Blade Cascade

distribution around a compressor aerofoil at low incidence for different levels of inlet Mach number. Once the local Mach number on the suction surface exceeds 1, additional losses arise due to the presence of shock waves. In addition, the rapid diffusion across the shock waves leads to thicker boundary layers and, thus, greater viscous losses. The higher diffusion on the suction surface at high inlet Mach number means that the blade boundary layers are likely to separate at modest levels of positive incidence.

**FIGURE 3.18**

Variation of Surface Mach Number with Inlet Mach Number for a C4 Compressor Blade at Low Incidence

In practice, the effects of high inlet Mach numbers are alleviated by using very thin blades and low camber. These features help to make the peak suction surface Mach number not much higher than the inlet Mach number. As shown in Chapter 5, such blades can be used for highly efficient transonic compressor rotors with relative inlet Mach numbers up to 1.5.

Figure 3.19 is a diagram showing the mean-line flow through a high speed compressor cascade. For any cascade, given the inlet angle, α_1 , the inlet Mach number, M_1 , and the exit Mach number, M_2 , it is possible to calculate the exit angle, and thus the deviation, if the cascade loss coefficient, Y_p , is known. This is done using the one-dimensional compressible flow relations for the flow through the cascade. The ratio of stagnation to static pressure and the non-dimensional mass flow are both functions of inlet Mach number:

$$\frac{p_{01}}{p_1} = \left(1 + \frac{\gamma - 1}{2} M_1^2\right)^{\gamma/(\gamma-1)}, \quad (\text{from eqn. 1.35})$$

$$\frac{\dot{m} \sqrt{C_p T_{01}}}{s H_1 \cos \alpha_1 p_{01}} = Q(M_1). \quad (\text{from eqn. 1.38})$$

From the definition of loss coefficient, Y_p (eqn. 3.5), the cascade stagnation pressure ratio can be found:

$$\frac{p_{02}}{p_{01}} = 1 - Y_p \left(1 - \frac{p_1}{p_{01}}\right). \quad (3.45)$$

FIGURE 3.19

Mean-Line Analysis of Compressible Flow through a Compressor Cascade

For a stationary blade row, $T_{01} = T_{02}$. Thus, the non-dimensional mass flow at exit from the cascade can be written:

$$\frac{\dot{m}\sqrt{C_P T_{02}}}{H_2 s \cos \alpha_2 p_{02}} = Q(M_2) = Q(M_1) \times \frac{H_1}{H_2} \times \frac{p_{01}}{p_{02}} \times \frac{\cos \alpha_1}{\cos \alpha_2}.$$

Assuming the AVDR of the cascade is equal to 1, then $H_1/H_2 = 1$, and the preceding can be written in the following form to give the flow exit angle:

$$\cos \alpha_2 = \frac{Q(M_1)}{Q(M_2)} \times \frac{p_{01}}{p_{02}} \times \cos \alpha_1. \quad (3.46)$$

Combining eqns. (3.45) and (3.46) gives the exit angle in terms of the inlet conditions, the loss coefficient, and the exit Mach number. Equally, the preceding expression can be used to find the exit Mach number or the loss coefficient in terms of the other quantities.

The effect of negative incidence at a high inlet Mach number can be demonstrated using an analysis similar to that presented previously to find when a compressor cascade will choke. Consider a compressor cascade with a minimum flow area, A^* , as pictured in Figure 3.20. This minimum flow area is usually referred to as the *throat* of the blade passage. Applying conservation of mass between the inlet and the throat,

$$\frac{\dot{m}\sqrt{C_P T_{01}}}{H_1 s \cos \alpha_1 p_{01}} = Q(M_1) = \frac{\dot{m}\sqrt{C_P T_{01}}}{A^* p_0^*} \times \frac{p_0^*}{p_{01}} \times \frac{A^*}{H_1 s \cos \alpha_1}. \quad (3.47)$$

When the flow chokes in the blade passage, the Mach number at the throat is unity and, therefore,

$$\frac{\dot{m}\sqrt{C_P T_{01}}}{A^* p_0^*} = Q(1) = \text{constant}.$$

In the best case, there will be little loss in stagnation pressure between inlet and the throat and $p_0^* = p_{01}$. In this case eqn. (3.47) can be simplified to give the inlet flow angle at which choking occurs:

$$\cos \alpha_1 = \frac{Q(1)}{Q(M_1)} \frac{A^*}{H_1 s}. \quad (3.48)$$

**FIGURE 3.20**

Choking of a Compressor Cascade at Negative Incidence

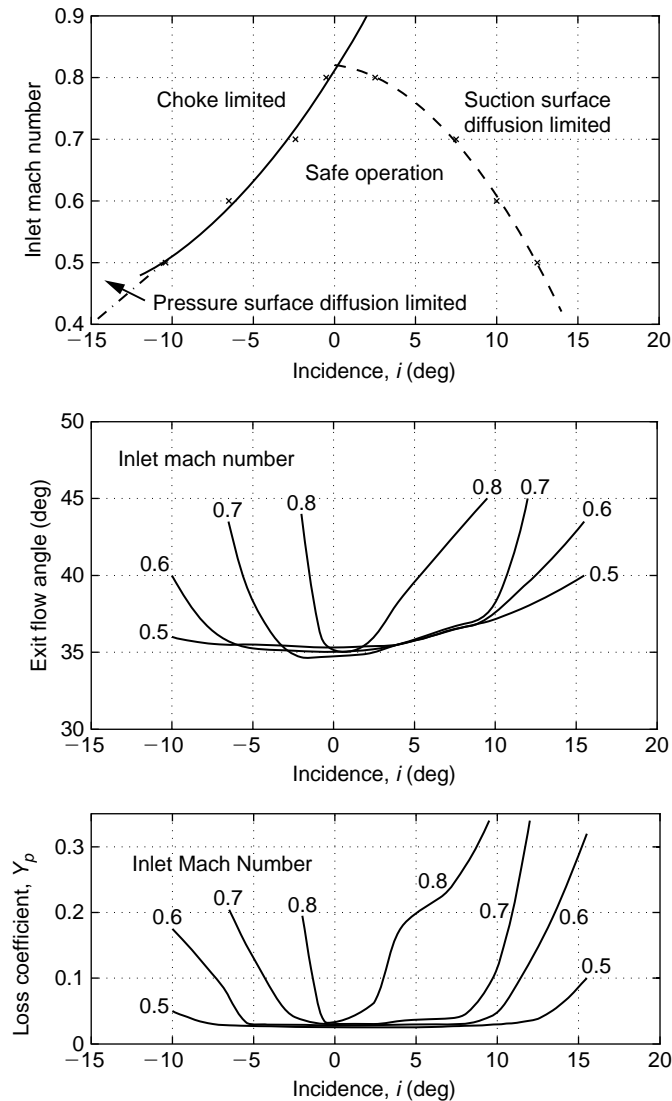

All the terms on the right-hand side of eqn. (3.48) are constant except $Q(M_1)$. This equation shows that, as the inlet Mach number increases, the cosine of the inlet angle when choking occurs decreases (and thus the actual angle increases). Therefore, the amount of negative incidence possible before choking occurs is reduced as the inlet Mach number increases. To avoid choking either the inlet angle must be increased or the inlet Mach number reduced.

To summarise, Figure 3.21 shows typical variations in loss coefficient and exit angle for a compressor cascade as a function of the inlet incidence angle and inlet Mach number. The exact form of these plots will depend on the detailed cascade geometry, but the trends shown are seen in all compressor blades. For a given inlet Mach number there is a range of incidence for which the cascade is low loss and low deviation. Outside this range, both the loss and deviation rise rapidly. The variation of a compressor blade row loss coefficient with incidence is often referred to as a *loss bucket* or a *loss loop*. The results plotted in Figure 3.21 clearly show that as Mach number increases the tolerance of the cascade to incidence is reduced. The reduced tolerance to positive incidence occurs due to the greater suction-surface diffusion present at higher inlet Mach numbers. The reduced tolerance to negative incidence occurs due to choking of the cascade blade passage. It is only at low inlet Mach numbers that diffusion on the pressure surface can limit the performance at high levels of negative incidence.

3.6 TURBINE CASCADES

There is a fundamental difference between the flow in turbine cascades and that in compressor cascades that needs emphasising. In turbine blade rows the pressure is falling and the flow is accelerating. This means that

- (i) the boundary layers are much more stable and remain attached to the blades;
- (ii) the blades can accept a much higher loading without the danger of boundary layer separation;
- (iii) the flow deflection in a turbine blade row can be greater than 120° ;
- (iv) the ratio of exit to inlet velocity, c_2/c_1 , can be between 2 and 4;
- (v) the diffusion factor on the suction surface, DF, is typically only about 0.15, so there is no danger of boundary layer separation except at very low values of Reynolds number.

**FIGURE 3.21**

Summary of Compressor Cascade Performance: Loss and Exit Flow Angle as a Function of Incidence and Mach Number

Figure 3.22 shows a sketch of the flow through an axial flow turbine cascade with the corresponding surface velocity distribution. This illustrates many of the features described previously and it is worth noting the rapid reduction in flow area through the cascade, which is what generates the high acceleration along the stream tube. The high acceleration and low levels of diffusion throughout the flow-field

**FIGURE 3.22**

Flow through an Axial Flow Turbine Cascade

lead to turbine cascades having a wide range of low loss performance. This is in contrast to compressor cascades, which have a rather narrow range. This is also the basic reason why turbines can have a much higher stage loading than compressors and why there are far fewer turbine stages than compressor stages in a turbojet engine.

Turbine Loss Correlations

A number of approaches have been made to predict the total pressure loss coefficients and flow deviation angles to the geometry of the turbine cascade and the incoming flow. A detailed account of the different methods and comparison of results found have been given by Horlock (1966), Dunham and Came (1970), Kacker and Okapuu (1981), Craig and Cox (1971), and others. In the following account it seems reasonable to limit the discussion to just two of the more prominent methods, namely,

- (i) the correlation of Ainley and Mathieson (1951);
- (ii) the correlation of Soderberg (1949).

Before embarking on the details of these correlations it seems only fair to mention that so far as their accuracy goes that Soderberg's method is adequate for making rapid estimates of turbine efficiency (which is dealt with in Chapter 4) and, according to Horlock (1966), can give efficiencies within $\pm 3\%$.

Correlation of Ainley and Mathieson

Ainley and Mathieson (1951) (A&M) reported a way of estimating the performance of an axial flow turbine, and it should be noted, the method has been widely used ever since. In essence the total pressure loss and gas efflux angle for each row of a turbine stage is determined at a single *reference* diameter and under a wide range of inlet conditions. This reference diameter was taken as the arithmetic mean of the rotor and stator rows' inner and outer diameters. Dunham and Came (1970) gathered together details of several improvements to the method, which gave better performance prediction for *small* turbines than did the original method. When the blading is *competently designed* the revised method has been found to give reliable predictions of efficiency to within $\pm 2\%$ over a wide range of designs, sizes, and operating conditions.

According to A&M's method the total pressure loss is composed of three parts:

- (i) a profile loss;
- (ii) a secondary loss;
- (iii) a tip clearance loss

and these are needed to determine the overall performance of a turbine stage.

In the following analysis we will be concerned only with the profile loss; the other two components of loss, which require fairly extensive descriptions, are considered in Chapter 4.

The profile loss coefficient, defined by eqn. (3.6), is determined initially at zero incidence ($i = 0$). At any other incidence the profile loss ratio $Y_p/Y_{p(i=0)}$ is assumed to be defined by a unique function of the incidence ratio i/i_s as shown in Figure 3.23, where i_s is the *stalling incidence*. Again, the stalling incidence is defined as the point where the profile loss ratio $Y_p/Y_{p(i=0)} = 2.0$.

Next, A&M correlated the profile losses of turbine blade rows against space–chord ratio s/l , fluid outlet angle α_2 , blade maximum thickness–chord ratio t_{\max}/l , and blade inlet angle. The variation of $Y_{p(i=0)}$ against the space–chord ratio s/l is shown in Figure 3.24(a) for *nozzle blade rows* and in Figure 3.24(b) for *impulse blading*, both at various flow outlet angles.

FIGURE 3.23

Variation of Profile Loss with Incidence for Typical Turbine Blading (Adapted from Ainley and Mathieson, 1951)

**FIGURE 3.24**

Profile Loss Coefficients of Turbine Nozzle and Impulse Blading at Zero Incidence ($t_{\max}/l = 0.2$; $\text{Re} = 2 \times 10^5$; $M < 0.6$) (Adapted from Ainley and Mathieson, 1951)

For the sort of blading normally employed (intermediate between nozzle blades and impulse blades) the zero incidence total pressure loss coefficient devised by A&M is

$$Y_{p(i=0)} = \left\{ Y_{p(\alpha_1=0)} + \left(\frac{\alpha_1}{\alpha_2} \right)^2 [Y_{p(\alpha_1=\alpha_2)} - Y_{p(\alpha_1=0)}] \right\} \left(\frac{t_{\max}/l}{0.2} \right)^{\alpha_1/\alpha_2}. \quad (3.49)$$

All the values of Y_p are taken at the same space-chord ratio and outlet flow angle. If rotor blades are being considered, put β_2 for α_1 and β_3 for α_2 . Equation (3.49) includes a correction for the effect of the thickness-chord ratio and is valid in the range $0.15 \leq t_{\max}/l \leq 0.25$. If the actual blade has a t_{\max}/l greater or less than the limits quoted, A&M recommended that the loss should be taken as equal to a blade having t_{\max}/l either 0.25 or 0.15.

A feature of the losses given in Figure 3.24 is that, compared with the impulse blades, the nozzle blades have a much lower total pressure loss coefficient. This observation confirms the results shown in Figure 3.25, that flows in which the mean pressure is falling always have a lower loss coefficient than flows in which the mean pressure is constant or increasing.

Reynolds Number Correction

A&M obtained their data for a mean Reynolds number of 2×10^5 based on the mean chord and exit flow conditions from the turbine state. They recommended that, for lower Reynolds numbers, down to 5×10^4 , a correction be made to stage efficiency according to the rough rule

$$(1 - \eta_{tt}) \propto \text{Re}^{-1/5}.$$

Soderberg's Correlation

A relatively simple method of estimating turbine blade row losses is to assemble the performance data on the overall efficiencies from a wide variety of turbines and from this determine the individual blade row stagnation pressure losses. Such a system was developed by Soderberg (1949) from a large number of tests performed on steam turbines and on cascades and extended to fit data obtained from small turbines with very low aspect ratio blading (small height–chord). Soderberg's method was intended only for turbines conforming to the standards of “good design,” discussed later.

Horlock (1960) critically reviewed several widely used methods of obtaining design data for turbines. His paper confirms the claim made for Soderberg's correlation that, although based on relatively few

FIGURE 3.25

Variation in Profile Loss with Incidence for Typical Turbine Cascade Blades (Adapted from Ainley, 1948)

parameters, its accuracy is comparable with the best of the other methods. Soderberg found that with the *optimum* space–chord ratio (using Zweifel’s criterion), turbine blade losses could be correlated with space–chord ratio, blade aspect ratio, blade thickness–chord ratio and Reynolds number.

For turbine blade rows operating at this load coefficient, with a Reynolds number of 10^5 and aspect ratio $H/b = \text{blade height/axial chord}$ of 3, the “nominal” loss coefficient, ζ^* (defined by eqn. 3.7) is a simple function of the fluid deflection angle, $\varepsilon = \alpha_1 + \alpha_2$, for a given thickness–chord ratio (t_{\max}/l):

$$\zeta^* = 0.04 + 0.06 \left(\frac{\varepsilon}{100} \right)^2, \quad (3.50)$$

where ε is in degrees. Values of ζ^* are drawn in Figure 3.26 as a function of deflection angle ε for several ratios of t_{\max}/l .

This expression fits the Soderberg curve (for $t_{\max}/l = 0.2$) quite well with $\varepsilon \leq 120^\circ$ but is less accurate at higher deflections. For turbine rows operating at zero incidence, which is the basis of Soderberg’s correlation, the fluid deflection is little different from the blading deflection since, for *turbine cascades*, deviations are usually small. If the aspect ratio H/b is other than 3, a correction to the nominal loss coefficient ζ^* is made as follows: for nozzle rows,

$$1 + \zeta_1 = (1 + \zeta^*)(0.993 + 0.021b/H), \quad (3.51a)$$

and for rotors,

$$1 + \zeta_1 = (1 + \zeta^*)(0.975 + 0.075b/H), \quad (3.51b)$$

where ζ_1 is the pressure loss coefficient at a Reynolds number of 10^5 .

A further correction can be made if the Reynolds number is different from 10^5 . As used in this section, the Reynolds number is based upon exit velocity c_2 and the hydraulic diameter D_h at the throat section, defined by

$$\text{Re} = \rho_2 c_2 D_h / \mu,$$

FIGURE 3.26

Soderberg’s Correlation of the Turbine Blade Loss Coefficient with Fluid Deflection (Adapted from Horlock, 1960)

where for a cascade geometry, $D_h = 2sH \cos \alpha_2 / (s \cos \alpha_2 + H)$. (Note: Mean diameter = $4 \times$ flow area \div perimeter.)

The Reynolds number correction is

$$\zeta_2 = \left(\frac{10^5}{\text{Re}} \right)^{1/4} \zeta_1. \quad (3.52)$$

Soderberg's method of loss prediction gives turbine efficiencies with an error of within $\pm 3\%$ over a wide range of Reynolds numbers and aspect ratios when additional corrections are included to allow for tip leakage and disc friction. The method was shown to be most useful by Lewis (1996) when applied to the performance analysis of axial-flow turbines and was also used by Sayers (1990).

The Zweifel Criterion

For turbine cascade blades there is an optimum space–chord ratio that gives a minimum overall loss. Figure 3.27 illustrates the way the velocity distribution varies around the surface of a turbine blade in a cascade at three values of space–chord ratio. If the spacing between the blades is made small, the fluid receives the maximum amount of guidance from the blades, but the friction losses will be large. On the other hand, with the same blades spaced well apart, friction losses are small but, because of poor fluid guidance, the losses resulting from flow separation are high. These considerations led Zweifel (1945) to formulate his criterion for the optimum space–chord ratio of turbine blades having large deflection angles. Essentially, *Zweifel's criterion* is simply that the ratio of an “actual” to an “ideal” tangential blade loading has an approximately constant value for minimum losses. The tangential blade loads are obtained from the real and ideal pressure distributions on both blade surfaces, as described here.

Figure 3.28 indicates a typical pressure distribution around one blade in an incompressible turbine cascade, curves P and S corresponding to the pressure (or concave) side and suction (convex) side, respectively. The pressures are projected parallel to the cascade front so that the area enclosed between the curves S and P represents the *actual tangential blade load*:

$$Y = \dot{m}(c_{y1} + c_{y2}). \quad (3.53)$$

FIGURE 3.27

Optimum Space–Chord Ratio for a Turbine Cascade

**FIGURE 3.28**

Typical Pressure Distribution around a Low Speed Turbine Cascade Blade

To give some idea of blade load capacity, the real pressure distribution is compared with an ideal pressure distribution giving a maximum load Y_{id} without risk of fluid separation on the S surface. The conditions for this ideal load are fulfilled by p_{01} acting over the *whole* P surface and p_2 acting over the *whole* S surface. With this pressure distribution the *ideal tangential load* is

$$Y_{id} = (p_{01} - p_2)bH, \quad (3.54)$$

where b is the axial chord of the blade. For incompressible, loss-free flow, $(p_{01} - p_2) = \frac{1}{2}\rho c_2^2$. If the axial velocity is also constant (i.e., $AVDR = 1$) then the mass flow, $\dot{m} = \rho H s c_x$, and the ratio of actual to ideal blade force is given by

$$Z = Y/Y_{id} = \frac{\dot{m}(c_{y1} + c_{y2})}{(p_{01} - p_2)bH} = \frac{\rho H s c_x^2 (\tan \alpha_1 + \tan \alpha_2)}{1/2 \rho c_x^2 \sec^2 \alpha_2 bH}.$$

This can be simplified to give

$$Z = Y/Y_{id} = 2(s/b) \cos^2 \alpha_2 (\tan \alpha_1 + \tan \alpha_2). \quad (3.55)$$

Zweifel found from a number of experiments on turbine cascades that at low Mach numbers, for minimum losses the value of Z was approximately 0.8. Thus, for specified inlet and outlet angles the optimum space–axial chord ratio is

$$s/b = 0.4 / [\cos^2 \alpha_2 (\tan \alpha_1 + \tan \alpha_2)]. \quad (3.56)$$

This shows that highly turning turbine blades, i.e., large $(\tan \alpha_1 + \tan \alpha_2)$, need to have a low pitch–axial chord ratio, whereas highly accelerating blades that have a high exit angle, i.e., small $\cos^2 \alpha_2$, can be spaced further apart.

According to Horlock (1966), Zweifel's criterion accurately predicts optimum space–chord ratio for the data of Ainley and Mathieson *only* for outlet angles of 60–70°. At other outlet angles the criterion gives a less accurate estimate of optimum space–axial chord ratio, a conclusion supported by Aungier

(2003). For modern blade designs, higher values of Z are common, particularly in the low pressure turbines of jet engines, where there is a need to minimize the overall turbine weight and thus reduce the number of aerofoils required. Japikse and Baines (1994) suggest that the value of Zweifel's coefficient used may be in excess of 1 in such cases.

For compressible flow turbine cascades, the assumptions used in deriving eqn. (3.55) are no longer valid and the compressible value of Z must be derived from eqns. (3.53) and (3.54), i.e.,

$$Z = Y/Y_{id} = \frac{\dot{m}(c_{y1} + c_{y2})}{(p_{01} - p_2)bH}.$$

The optimum value of Z , as just defined, is found to decrease as the exit Mach number rises. This reduction occurs because the ideal dynamic pressure $(p_{01} - p_2)$ increases rapidly with Mach number leading to a larger ideal blade force. For high Mach numbers the coefficient can be evaluated using compressible flow relations as demonstrated in Example 3.4.

Example 3.4

A two-dimensional linear turbine cascade operates in air with an inlet flow angle of 22° and an inlet Mach number of 0.3. The exit Mach number is measured as 0.93 with an exit flow angle of 61.4° . Calculate the ratio of inlet stagnation pressure to exit static pressure and determine the cascade stagnation pressure loss coefficient. If, for this operating condition, the Zweifel loading coefficient required for the cascade is 0.6, determine the pitch to axial chord ratio for the blades.

Solution

Applying continuity from inlet to exit of the cascade,

$$\frac{\dot{m}\sqrt{c_p T_{01}}}{H \cos \alpha_1 p_{01}} = Q(M_1) = \frac{\dot{m}\sqrt{c_p T_{02}}}{H \cos \alpha_2 p_{02}} \times \frac{\cos \alpha_2}{\cos \alpha_1} \times \frac{p_{02}}{p_{01}}.$$

For a cascade, the stagnation temperature is constant, and thus, $T_{02} = T_{01}$. Rearranging the preceding equation allows the stagnation pressure ratio to be found by using compressible flow tables:

$$\frac{p_{02}}{p_{01}} = \frac{Q(M_1)}{Q(M_2)} \times \frac{\cos \alpha_1}{\cos \alpha_2} = \frac{0.6295}{1.2756} \times \frac{\cos(22^\circ)}{\cos(61.4^\circ)} = 0.9559.$$

The ratio of inlet stagnation to exit pressure is found from

$$\frac{p_{01}}{p_2} = \frac{p_{01}}{p_2} \times \frac{p_{01}}{p_{02}} = \frac{1}{0.5721 \times 0.9559} = 1.829.$$

The cascade loss coefficient can then be determined:

$$Y_P = \frac{p_{01} - p_{02}}{p_{01} - p_2} = \frac{1 - p_{02}/p_{01}}{1 - p_2/p_{01}} = \frac{1 - 0.9559}{1 - 1.829^{-1}} = \underline{0.0973}.$$

The Zweifel coefficient can be expressed in terms of non-dimensional groups that are each a function of Mach number. By expressing the Zweifel coefficient in this way, the compressible flow tables can then be used to evaluate each of the parameters required:

$$Z = \frac{\dot{m}(c_{y1} + c_{y2})}{(p_{01} - p_2)bH} = \frac{\dot{m}\sqrt{c_p T_{01}}}{Hs \cos \alpha_1 p_{01}} \times \frac{(c_1 \sin \alpha_1 / \sqrt{c_p T_{01}} + c_2 \sin \alpha_2 / \sqrt{c_p T_{01}}) \times Hs \cos \alpha_1}{(1 - p_2/p_{01})bH}.$$

The Zweifel coefficient is then simplified to the following function of the blade pitch to axial chord ratio, the inlet and exit Mach numbers and the flow angles:

$$Z = Q(M_1) \times \frac{(c_1 / \sqrt{c_p T_{01}} \times \sin \alpha_1 + c_2 / \sqrt{c_p T_{01}} \times \sin \alpha_2) \times \cos \alpha_1}{(1 - p_2/p_{01})} \times \frac{s}{b}.$$

Rearranging this equation to find the pitch to axial chord ratio gives

$$\frac{s}{b} = \frac{(1 - p_2/p_{01})Z}{Q(M_1) \times (c_1 / \sqrt{c_p T_{01}} \times \sin \alpha_1 + c_2 / \sqrt{c_p T_{01}} \times \sin \alpha_2) \times \cos \alpha_1}.$$

Putting in the values and using the compressible flow tables where needed,

$$\frac{s}{b} = \frac{(1 - 1.829^{-1}) \times 0.6}{0.6295 \times [0.1881 \times \sin(22^\circ) + 0.5431 \times \sin(61.4^\circ)] \times \cos(22^\circ)} = \underline{0.851}.$$

Flow Exit Angle

For turbine blades the low amount of diffusion on the suction surface together with the thin boundary layers imply that the flow exit angle is much closer to the metal angle at the trailing edge than for a compressor cascade blade. (i.e., a small deviation angle). However, accurate prediction of the exit angle is extremely important because the downstream flow area, $Hs \cos \alpha_2$, varies rather rapidly with the exit angle α_2 .

At high Mach numbers the flow exit angle can be determined from compressible flow relationships. Figure 3.29 shows the flow through a choked turbine cascade. When the blade throat is choked the mass average Mach number across the throat is unity, in which case, (referring to eqn. 1.38):

$$\frac{\dot{m}\sqrt{c_p T_0}}{Hop_o^*} = Q(1), \quad (3.57)$$

where o is the minimum distance at the blade throat, as shown in Figure 3.29, and p_o^* is the stagnation pressure at that location. Once the flow is choked, conditions upstream of the throat are fixed and independent of the downstream pressure.

Downstream of the cascade the flow area is $s \cos \alpha_2$ and the Mach number is M_2 ,

$$\frac{\dot{m}\sqrt{c_p T_0}}{Hs \cos \alpha_2 p_{02}} = Q(M_2); \quad (3.58)$$

**FIGURE 3.29**

Flow through a Choked Turbine Cascade

hence, by combining the preceding two equations,

$$\cos \alpha_2 = \frac{Q(1)}{Q(M_2)} \times \frac{p_0^*}{p_{02}} \times \frac{o}{s}. \quad (3.59)$$

If the losses downstream of the throat are small then $p_{02} \approx p_0^*$, so

$$\cos \alpha_2 = \frac{Q(1)}{Q(M_2)} \times \frac{o}{s}. \quad (3.60)$$

In particular, when $M_2 = 1$, then $\alpha_2 = \cos^{-1}(o/s)$.

Figure 3.30 indicates how the angle α_2 varies from subsonic to supersonic flow. For subsonic flows the exit angle varies very little with Mach number. For supersonic exit flows, $Q(M_2) < Q(1)$ and it follows from eqn. (3.60) that α_2 decreases. This is known as *supersonic deviation*. As shown by Figure 3.30, further deviation is observed in experimental measurements. The additional deviation relative to the theory is caused by stagnation pressure losses downstream of the throat, $p_{02} < p_0^*$ and the blockage caused by the growth of boundary layers on the blade surfaces.

Figure 3.31 shows plots of how the various components of loss coefficient, ζ , vary with exit Mach number, M_2 , for a typical high-speed turbine cascade, taken from Mee et al. (1992). This plot

**FIGURE 3.30**

The Variation of Exit Flow Angle with Exit Mach Number for a Transonic Turbine Cascade

**FIGURE 3.31**

Variation of Loss Coefficient with Mach Number for a Turbine Cascade at a Reynolds Number of 1×10^6 (from Mee et al., 1992)

demonstrates how the loss coefficient of a turbine blade rises rapidly as M_2 approaches and exceeds unity. This rise in loss is closely related to the thickness of the blade trailing edge. It is partly caused by the shock waves but it is also due to mixing and the complex trailing edge flow pattern. This pattern generates a low pressure region at the trailing edge, causing a drag force to act on the blade. This is investigated in detail within Sieverding, Richard, and Desse (2003).

Turbine Limit Load

Turbines frequently operate with supersonic exit flows and at such conditions shock waves emanate from the trailing edge. One branch of the shock wave propagates downstream but the other branch reflects off the suction surface of the adjacent blade. The configuration of these shock waves is shown in Figure 3.32 using a Schlieren photograph of the flow in a transonic turbine cascade at a downstream Mach number, $M_2 = 1.15$.

The back pressure of the cascade can be lowered until the axial velocity component of the exit flow is equal to the sonic speed. This condition is called the *limit load* and is the point where information

FIGURE 3.32

Schlieren Photograph of Flow in a Highly Loaded Transonic Turbine Cascade with an Exit Mach Number of 1.15 (from Xu, 1985)

(i.e., pressure waves) cannot travel upstream. At *limit load*, $M_{x,\text{lim}} = M_{2,\text{lim}} \cos \alpha_{2,\text{lim}} = 1.0$, which implies that

$$M_{2,\text{lim}} = \frac{1}{\cos \alpha_{2,\text{lim}}} . \quad (3.61)$$

Conservation of mass means that

$$\frac{\dot{m} \sqrt{c_p T_0}}{H s \cos \alpha_{2,\text{lim}} p_{02}} = Q(M_{2,\text{lim}}) = \frac{\dot{m} \sqrt{c_p T_0}}{H o p_o^*} \times \frac{p_o^*}{p_{02}} \times \frac{o}{s \cos \alpha_{2,\text{lim}}} .$$

Given that the throat is choked, as in eqn. (3.57),

$$\frac{\dot{m} \sqrt{c_p T_0}}{H o p_o^*} = Q(1),$$

so that

$$Q(M_{2,\text{lim}}) = Q(1) \times \frac{p_o^*}{p_{02}} \times \frac{o}{s \cos \alpha_{2,\text{lim}}} . \quad (3.62)$$

Equations (3.61) and (3.62) can be solved simultaneously to enable both $M_{2,\text{lim}}$ and $\alpha_{2,\text{lim}}$ to be determined. Typically, the range of maximum exit Mach number is $1.4 < M_{2,\text{lim}} < 2.0$.

PROBLEMS

1. Experimental compressor cascade results suggest that the stalling lift coefficient of a cascade blade may be expressed as

$$C_L \left(\frac{c_1}{c_2} \right)^3 = 2.2,$$

where c_1 and c_2 are the entry and exit velocities. Find the stalling inlet angle for a compressor cascade of space–chord ratio unity if the outlet air angle is 30° .

2. Show, for a turbine cascade, using the angle notation of Figure 3.28, that the lift coefficient is

$$C_L = 2(s/l)(\tan \alpha_1 + \tan \alpha_2) \cos \alpha_m + C_D \tan \alpha_m,$$

where $\tan \alpha_m = \frac{1}{2}(\tan \alpha_m - \tan \alpha_1)$ and $C_D = \text{drag}/(\frac{1}{2}\rho c_m^2 l)$. A cascade of turbine nozzle vanes has a blade inlet angle α'_1 of 0° , a blade outlet angle α'_2 of 65.5° , a chord length l of 45 mm and an axial chord b of 32 mm. The flow entering the blades is to have zero incidence and an estimate of the deviation angle based upon similar cascades is that δ will be about 1.5° at low outlet Mach number. If the blade load ratio Z defined by eqn. (3.55) is to be 0.85, estimate a suitable space–chord ratio for the cascade. Determine the drag and lift coefficients for the cascade given that the profile loss coefficient is

$$\lambda = \Delta p_0 / \left(\frac{1}{2} \rho c_2^2 \right) = 0.035.$$

3. A compressor cascade is to be designed for the following conditions:

Nominal fluid outlet angle: $\alpha_2^* = 30^\circ$

Cascade camber angle: $\theta = 30^\circ$

Pitch/chord ratio: $s/l = 1.0$

Circular arc camber line: $a/l = 0.5$

Using Howell's curves and his formula for nominal deviation, determine the nominal incidence, the actual deviation for an incidence of $+2.7^\circ$ and the approximate lift coefficient at this incidence.

4. A compressor cascade is built with blades of circular arc camber line, a space–chord ratio of 1.1 and blade angles of 48° and 21° at inlet and outlet. Test data taken from the cascade shows that at zero incidence ($i = 0$) the deviation $\delta = 8.2^\circ$ and the total pressure loss coefficient $\bar{w} = \Delta p_0 / (\frac{1}{2} \rho c_1^2) = 0.015$. At positive incidence over a limited range ($0 \leq i \leq 6^\circ$) the variation of both δ and \bar{w} for this particular cascade can be represented with sufficient accuracy by linear approximations:

$$\frac{d\delta}{di} = 0.06, \quad \frac{d\bar{w}}{di} = 0.001,$$

where i is in degrees. For a flow incidence of 5.0° determine

- (i) the flow angles at inlet and outlet;
- (ii) the diffuser efficiency of the cascade;
- (iii) the static pressure rise of air with a velocity 50 m/s normal to the plane of the cascade.

Assume density of air is 1.2 kg/m^3 .

5. (a) A cascade of compressor blades is to be designed to give an outlet air angle α_2 of 30° for an inlet air angle α_1 of 50° measured from the normal to the plane of the cascade. The blades are to have a *parabolic arc* camber line with $a/l = 0.4$ (i.e., the fractional distance along the chord to the point of maximum camber). Determine the space–chord ratio and blade outlet angle if the cascade is to operate at zero incidence and nominal conditions. You may assume the linear approximation for nominal deflection of Howell's cascade correlation:

$$\varepsilon^* = (16 - 0.2\alpha_2^*)(3 - s/l) [\text{degrees}],$$

as well as the formula for nominal deviation:

$$\delta^* = \left[0.23 \left(\frac{2a}{l} \right)^2 + \frac{\alpha_2^*}{500} \right] \theta \sqrt{\frac{s}{l}} [\text{degrees}].$$

- (b) The space–chord ratio is now changed to 0.8, but the blade angles remain as they are in part (a). Determine the lift coefficient when the incidence of the flow is 2.0° . Assume that there is a linear relationship between $\varepsilon/\varepsilon^*$ and $(i - i^*)/\varepsilon^*$ over a limited region, viz. at $(i - i^*)/\varepsilon^* = 0.2$, $\varepsilon/\varepsilon^* = 1.15$, and at $i = i^*$, $\varepsilon/\varepsilon^* = 1$. In this region take $C_D = 0.02$.
6. (a) Show that the pressure rise coefficient $C_p = \Delta p / (\frac{1}{2} \rho c_1^2)$ of an incompressible compressor cascade is related to the total pressure loss coefficient ζ by the following expression:

$$C_p = 1 - (\sec^2 \alpha_2 + \zeta) / \sec^2 \alpha_1,$$

$$\zeta = \Delta p_0 / \left(\frac{1}{2} \rho c_x^2 \right),$$

where α_1, α_2 = flow angles at cascade inlet and outlet.

- (b) Determine a suitable *maximum* inlet flow angle of a low speed compressor cascade having a space–chord ratio 0.8 and $\alpha_2 = 30^\circ$ when the diffusion factor DF is limited to 0.6. The definition of diffusion factor that should be used is the early Lieblein formula (1959):

$$DF = \left(1 - \frac{\cos \alpha_1}{\cos \alpha_2} \right) + \left(\frac{s}{l} \right) \frac{\cos \alpha_1}{2} (\tan \alpha_1 - \tan \alpha_2).$$

- (c) The stagnation pressure loss derived from flow measurements on this cascade is 149 Pa when the inlet velocity c_1 is 100 m/s at an air density ρ of 1.2 kg/m^3 . Determine the values of
- (i) pressure rise and
 - (ii) drag and lift coefficients.

7. A two-dimensional compressor cascade is tested in air with an inlet stagnation pressure of 1 bar and an inlet stagnation temperature of 300 K. For an inlet Mach number of 0.75 and an inlet flow angle of 50° , the exit flow angle is measured as 15.8° . Determine the mass flow rate per unit frontal area. Assuming the flow is isentropic, calculate the exit Mach number and the static pressure ratio across the cascade.
8. A compressor blade design tested in a cascade is found to choke with an inlet Mach number of 0.9 when the inlet flow angle is 52° . If the ratio of the throat area to the frontal area, A^*/H_{1s} , for the cascade is 0.625, calculate the loss of stagnation pressure between the far upstream and the throat and express this as a loss coefficient. Comment on what could cause this loss.
9. A turbine cascade operates in air with an inlet angle of 45° from the axial direction. The ratio of inlet stagnation pressure to exit static pressure is 2.6 and the inlet Mach number is 0.3.
 - (a) If the stagnation pressure loss coefficient, Y_p , is measured to be 0.098, calculate the exit Mach number and show that the exit angle is 67.7° . It can be assumed that the blade height is constant through the cascade and that the growth of sidewall boundary layers is negligible.
 - (b) The opening to pitch ratio of the cascade is 0.354. For the operating point described in part (a), show that approximately two thirds of the total loss in stagnation pressure occurs downstream of the throat.
 - (c) The exit static pressure from the cascade is lowered until limit load is achieved. The exit Mach number at this condition is measured to be 1.77. Given that the stagnation pressure loss upstream of the throat is unchanged, determine the new overall stagnation pressure loss coefficient for the cascade.

Axial-Flow Turbines: Mean-Line Analysis and Design

Power is more certainly retained by wary measures than by daring counsels.

Tacitus, *Annals*

4.1 INTRODUCTION

The modern axial-flow turbine developed from a long line of inventions stretching back in time to the aeolipile of Heron (aka Hero) of Alexandria around 120 B.C. Although we would regard it as a toy it did demonstrate the important principle that rotary motion could be obtained by the expansion of steam through nozzles. Over the centuries many developments of rotary devices took place with wind and water driven mills, water driven turbines, and the early steam turbine of the Swedish engineer Carl de Laval in 1883. The main problems of the de Laval turbines arose from their enormous rotational speeds, the smallest rotors attained speeds of 26,000 rpm and the largest had peripheral speeds in excess of 400 m/s. Learning from these mistakes, Sir Charles Parsons in 1891 developed a multi-stage (15 stages) axial-flow steam turbine, which had a power output of 100 kW at 4800 rpm. Later, and rather famously, a Parsons steam turbine rated at 1570 kW was used to power a 30 m long ship, Turbinia, at what was regarded as an excessive speed at a grand review of naval ships at Spithead, England, in 1897. It outpaced the ships ordered to pursue it and to bring order to the review. This spectacular dash at once proved to all the capability and power of the steam turbine and was a turning point in the career of Parsons and for the steam turbine. Not long after this most capital ships of the major powers employed steam turbines rather than old-fashioned piston engines.

From this point on the design of steam turbines evolved rapidly. By 1920 General Electric was supplying turbines rated at 40 MW for generating electricity. Significant progress has since been made in the size and efficiency of steam turbines with 1000 MW now being achieved for a single shaft plant. Figure 4.1 shows the rotor of a modern double-flow low pressure turbine with this power output.

The development of the axial-flow turbine is tied to the history of the aircraft gas turbine but clearly depended upon the design advances made previously in the field of steam turbines. In this chapter the basic thermodynamic and aerodynamic characteristics of axial-flow turbines are presented. The simplest approach to their analysis is to assume that the flow conditions at a mean radius, called the *pitchline*, represent the flow at all radii. This two-dimensional analysis can provide a reasonable approximation to the actual flow, provided that the ratio of blade height to mean radius is small.

**FIGURE 4.1**

Large Low Pressure Steam Turbine (with kind permission of Siemens Turbines)

However, when this ratio is large, as in the final stages of an aircraft or a steam turbine, a more elaborate *three-dimensional analysis* is necessary. Some elementary three-dimensional analyses of the flow in axial turbomachines of low hub-to-tip ratio, e.g., $r_h/r_t \approx 0.4$, are discussed in Chapter 6. One further assumption required for the purposes of mean line analysis is that the flow is invariant along the circumferential direction (i.e., there are no significant “blade-to-blade” flow variations).

For turbines the analysis is presented with compressible flow effects in mind. This approach is then applicable to both steam and gas turbines provided that, in the former case, the steam condition remains wholly within the *vapour* phase (i.e., superheat region).

The modern axial-flow turbine used in aircraft engines now lies at the extreme edge of technological development; the gases leaving the combustor can be at temperatures of around 1600°C or more whilst the material used to make turbine blades melt at about 1250°C . Even more remarkable is the fact that these blades are subjected to enormous centrifugal forces and bending loads from deflecting the hot gases. The only way these temperature and stress levels can be sustained is by an adequate cooling system of HP air supplied from the final stage compressor. In this chapter a brief outline of the basic ideas on centrifugal stresses and some of the methods used for blade cooling is given. Figure 4.2 shows the three shaft axial-flow turbine system of a Rolls Royce Trent turbofan engine.

**FIGURE 4.2**

Turbine Module of a Modern Turbofan Jet Engine (with kind permission from Rolls-Royce plc)

4.2 VELOCITY DIAGRAMS OF THE AXIAL-TURBINE STAGE

The axial turbine stage comprises a row of fixed guide vanes or nozzles (often called a *stator* row) and a row of moving blades or buckets (a *rotor* row). Fluid enters the stator with absolute velocity c_1 at angle α_1 and accelerates to an absolute velocity c_2 at angle α_2 (Figure 4.3). All angles are measured from the axial (x) direction. The *sign convention* is such that angles and velocities as drawn in Figure 4.3 will be taken as positive throughout this chapter. From the velocity diagram, the rotor inlet *relative* velocity w_2 , at an angle β_2 , is found by subtracting, vectorially, the blade speed U from the absolute velocity c_2 . The relative flow within the rotor accelerates to velocity w_3 at an angle β_3 at rotor outlet;

**FIGURE 4.3**

Turbine Stage Velocity Diagrams

the corresponding absolute flow (c_3, α_3) is obtained by adding, vectorially, the blade speed U to the relative velocity w_3 .

When drawing the velocity triangles it is always worth sketching the nozzle and rotor rows beside them, as shown in Figure 4.3. This helps prevent errors, since the absolute velocities are roughly aligned with the inlet and exit angles from the nozzle row and the relative velocities are aligned with the rotor row. Note that, within an axial turbine, the levels of turning are very high and the flow is turned through the axial direction in both the rotors and nozzles.

The continuity equation for uniform, steady flow is

$$\rho_1 A_{x1} c_{x1} = \rho_2 A_{x2} c_{x2} = \rho_3 A_{x3} c_{x3}. \quad (4.1)$$

4.3 TURBINE STAGE DESIGN PARAMETERS

Three key non-dimensional parameters are related to the shape of the turbine velocity triangles and are used in fixing the preliminary design of a turbine stage.

Design Flow Coefficient

This was introduced in Chapter 2. It is strictly defined as the ratio of the meridional flow velocity to the blade speed, $\phi = c_m/U$, but in a purely axial flow machine, $\phi = c_x/U$. The value of ϕ for a stage determines

the relative flow angles. A stage with a low value of ϕ implies highly staggered blades and relative flow angles close to tangential. High values imply low stagger and flow angles closer to axial. For a fixed geometry and fixed rotational speed, the mass flow through the turbine increases with increasing ϕ .

Stage Loading Coefficient

The stage loading is defined as the ratio of the stagnation enthalpy change through a stage to the square of the blade speed, $\psi = \Delta h_0 / U^2$. In an adiabatic turbine, the stagnation enthalpy change is equal to the specific work, ΔW , and for a purely axial turbine with constant radius, we can use the Euler work equation (eqn. 1.19b) to write $\Delta h_0 = U \Delta c_\theta$. The stage loading can therefore be written as

$$\psi = \Delta c_\theta / U, \quad (4.2)$$

where Δc_θ represents the change in the tangential component of absolute velocity through the rotor. Thus, high stage loading implies large flow turning and leads to highly “skewed” velocity triangles to achieve this turning. Since the stage loading is a non-dimensional measure of the work extraction per stage, a high stage loading is desirable because it means fewer stages are needed to produce a required work output. However, as shown in later sections of this chapter, the stage loading is limited by the effects that high stage loadings have on efficiency.

Stage Reaction

The stage reaction is defined as the ratio of the static *enthalpy* drop in the rotor to the static *enthalpy* drop across the stage. Thus,

$$R = (h_2 - h_3) / (h_1 - h_3). \quad (4.3a)$$

Taking the flow through a turbine as *nearly* isentropic the equation of the second law of thermodynamics, $Tds = dh - dp/\rho$ can be approximated by $dh = dp/\rho$, and ignoring compressibility effects, the reaction can thus be approximated as

$$R \approx (p_2 - p_3) / (p_1 - p_3). \quad (4.3b)$$

The reaction therefore indicates the drop in pressure across the rotor compared to that for the stage. However, as a design parameter, the reaction is more significant since it describes the asymmetry of the velocity triangles and is therefore a statement of the blade geometries. As will be shown later, a 50% reaction turbine implies velocity triangles that are symmetrical, which leads to similar stator and rotor blade shapes. In contrast, a zero reaction turbine stage implies little pressure change through the rotor. This requires rotor blades that are highly cambered, that do not accelerate the relative flow greatly, and low cambered stator blades that produce highly accelerating flow.

4.4 THERMODYNAMICS OF THE AXIAL-TURBINE STAGE

The work done on the rotor by unit mass of fluid, the specific work, equals the stagnation enthalpy drop incurred by the fluid passing through the stage (assuming adiabatic flow). From the Euler work equation (1.19a), we can write

$$\Delta W = \dot{W} / \dot{m} = h_{01} - h_{03} = U(c_{\theta 2} + c_{\theta 3}). \quad (4.4)$$

In eqn. (4.4) the absolute tangential velocity components (c_θ) are *added*, so as to adhere to the agreed sign convention of Figure 4.3. As no work is done in the nozzle row, the stagnation enthalpy across it remains constant and

$$h_{01} = h_{02}. \quad (4.5)$$

In an axial turbine, the radial component of velocity is small. Writing $h_0 = h + \frac{1}{2}(c_x^2 + c_\theta^2)$ and using eqn. (4.5) in eqn. (4.4) we obtain

$$h_{02} - h_{03} = (h_2 - h_3) + \frac{1}{2}(c_{\theta 2}^2 - c_{\theta 3}^2) + \frac{1}{2}(c_{x2}^2 - c_{x3}^2) = U(c_{\theta 2} + c_{\theta 3}),$$

hence,

$$(h_2 - h_3) + \frac{1}{2}(c_{\theta 2} + c_{\theta 3})[(c_{\theta 2} - U) - (c_{\theta 3} + U)] + \frac{1}{2}(c_{x2}^2 - c_{x3}^2) = 0.$$

It is observed from the velocity triangles of Figure 4.3 that $c_{\theta 2} - U = w_{\theta 2}$, $c_{\theta 3} + U = w_{\theta 3}$ and $c_{\theta 2} + c_{\theta 3} = w_{\theta 2} + w_{\theta 3}$. Thus,

$$(h_2 - h_3) + \frac{1}{2}(w_{\theta 2}^2 - w_{\theta 3}^2) + \frac{1}{2}(c_{x2}^2 - c_{x3}^2) = 0.$$

This equation can be reduced to

$$h_2 + \frac{1}{2}w_2^2 = h_3 + \frac{1}{2}w_3^2 \text{ or } h_{02,\text{rel}} = h_{03,\text{rel}}. \quad (4.6)$$

Thus, the *relative* stagnation enthalpy, $h_{0,\text{rel}} = h + \frac{1}{2}w^2$, remains unchanged through the rotor of a purely axial turbomachine. It is assumed that no radial shift of the streamlines occurs in this flow. In some modern axial turbines the mean flow may have a component of radial velocity, and in this case the more general form of the Euler work equation must be used to account for changes in the blade speed perceived by the flow, see eqn. (1.21a). It is then the *rothalpy* that is conserved through the rotor,

$$h_2 + \frac{1}{2}w_2^2 - \frac{1}{2}U_2^2 = h_3 + \frac{1}{2}w_3^2 - \frac{1}{2}U_3^2 \text{ or } I_2 = I_3 \quad (4.7)$$

where U_2 and U_3 are the local blade speeds at inlet and outlet from the rotor, $U_2 = r_2\Omega$ and $U_3 = r_3\Omega$. Within the rest of this chapter, the analysis presented is directed at purely axial turbines that have a constant mean flow radius and therefore a single blade speed.

A Mollier diagram showing the change of state through a complete turbine stage, including the effects of irreversibility, is given in Figure 4.4.

Through the nozzles, the state point moves from 1 to 2 and the static pressure decreases from p_1 to p_2 . In the rotor row, the absolute static pressure reduces (in general) from p_2 to p_3 . It is important to note that all the conditions contained in eqns. (4.4)–(4.6) are satisfied in the figure.

FIGURE 4.4

Mollier Diagram for a Turbine Stage

4.5 REPEATING STAGE TURBINES

Aero-engine and power generation applications require turbines with high power output and high efficiency. To achieve this, an axial turbine with multiple stages is required. In these multi-stage axial-flow turbines, the design is often chosen to have identical, or at least very similar, mean velocity triangles for all stages. To achieve this, the axial velocity and the mean blade radius must remain constant throughout the turbine. To allow for the reduction in fluid density that arises as the flow expands through the turbine, the blade height must be continuously increasing between blade rows. Figure 4.5 shows the arrangement of a multi-stage turbine within an aero-engine, showing the increasing blade height and the constant mean radius.

For the velocity diagrams to be the same, the flow angles at exit from each stage must be equal to those at the inlet. The requirements for a *repeating stage* can therefore be summarized as

$$c_x = \text{constant}, r = \text{constant}, \alpha_1 = \alpha_3.$$

Note that a single stage turbine can also satisfy these conditions for a repeating stage. Stages satisfying these requirements are often referred to as *normal* stages.

For this type of turbine, several useful relationships can be derived relating the shapes of the velocity triangles to the flow coefficient, stage loading, and reaction parameters. These relationships are important for the preliminary design of the turbine.

**FIGURE 4.5**

General Arrangement of a Repeating Six-Stage Turbine

Starting with the definition of reaction,

$$R = (h_2 - h_3)/(h_1 - h_3) = 1 - (h_1 - h_2)/(h_{01} - h_{03}). \quad (4.8)$$

Note that $h_{01} - h_{03} = h_1 - h_3$ since the inlet and exit velocities for the stage are equal. Through the stator no work is done, so the stagnation enthalpy stays constant across it. Given that the axial velocity is also constant this gives

$$(h_1 - h_2) = (h_{01} - h_{02}) + \frac{1}{2}(c_2^2 - c_1^2) = \frac{1}{2}c_x^2(\tan^2 \alpha_2 - \tan^2 \alpha_1). \quad (4.9)$$

From the definition of stage loading,

$$(h_{01} - h_{03}) = U^2 \psi. \quad (4.10)$$

Substituting these in the equations for the reaction (4.3) and by applying the definition of flow coefficient for a purely axial turbine, $\phi = c_x/U$, the following is obtained:

$$R = 1 - \frac{\phi^2}{2\psi}(\tan^2 \alpha_2 - \tan^2 \alpha_1). \quad (4.11)$$

This is true whether or not the exit angle from the stage equals the inlet angle. It shows how the three non-dimensional design parameters are related to the flow angles at inlet and exit from the turbine nozzle. In a repeating stage turbine this relationship can be further simplified, since the stage loading can be written as follows:

$$\psi = \frac{\Delta c_\theta}{U} = \frac{c_x(\tan \alpha_2 + \tan \alpha_3)}{U} = \phi(\tan \alpha_2 + \tan \alpha_1). \quad (4.12)$$

Substituting this into equation (4.11) we obtain

$$R = 1 - \frac{\phi}{2}(\tan \alpha_2 - \tan \alpha_1). \quad (4.13a)$$

This can be combined with eqn. (4.12) to eliminate α_2 . Adding $2 \times$ eqn. (4.13a) to eqn (4.12) gives the following relationship between stage loading, flow coefficient, and reaction:

$$\psi = 2(1 - R + \phi \tan \alpha_1). \quad (4.14)$$

This is a very useful result. It also applies to repeating stages of compressors. It shows that, for high stage loading, ψ , the reaction, R , should be low and the inter-stage swirl angle, $\alpha_1 = \alpha_3$, should be as large as possible. Equations (4.13a) and (4.14) also show that, once the stage loading, flow coefficient, and reaction are fixed, all the flow angles, and thus the velocity triangles, are fully specified. This is true since eqn. (4.14) gives α_1 , and α_2 then follows from eqn. (4.13). The other angles of the velocity triangles are then fixed from the repeating stage condition, $\alpha_1 = \alpha_3$, and the relationship between relative and absolute flow angles,

$$\tan \beta_2 = \tan \alpha_2 - \frac{1}{\phi}, \quad \tan \beta_3 = \tan \alpha_3 + \frac{1}{\phi}. \quad (4.15)$$

Note that by combining eqn. (4.15) with eqn. (4.13a) another useful equation for the reaction can be formed in terms of the relative flow angles,

$$R = \frac{\phi}{2} (\tan \beta_3 - \tan \beta_2). \quad (4.13b)$$

In summary, to fix the velocity triangles for a *repeating stage* a turbine designer can fix ϕ , ψ , and R or ϕ , ψ , and α_1 (or indeed any independent combination of three angles and parameters). Once the velocity triangles are fixed, key features of the turbine design can be determined, such as the turbine blade sizes and the number of stages needed. The expected performance of the turbine can also be estimated. These aspects of the preliminary design are considered further in section 4.7.

Note also that the choice of the velocity triangles for the turbine (i.e., the choice of ϕ , ψ , and R) are largely determined by best practice and previous experience. For a company that has already designed and tested many turbines of a similar style, it will be very challenging to produce a turbine with very different values of ϕ , ψ , and R that has as good performance as its previous designs.

4.6 STAGE LOSSES AND EFFICIENCY

In Chapter 1 various definitions of efficiency for complete turbomachines were given. For a *turbine stage* the total-to-total efficiency is

$$\eta_{tt} = \frac{\text{actual work output}}{\text{ideal work output when operating to same back pressure}} = (h_{01} - h_{03}) / (h_{01} - h_{03ss}).$$

At the entry and exit of a repeating (or *normal*) stage, the flow conditions (absolute velocity and flow angle) are identical, i.e., $c_1 = c_3$ and $\alpha_1 = \alpha_3$. If it is assumed that $c_{3ss} = c_3$, which is a reasonable approximation for turbines operating with a fairly low pressure ratio, the total-to-total efficiency then becomes

$$\eta_{tt} = (h_1 - h_3) / (h_1 - h_{3ss}) = (h_1 - h_3) / [(h_1 - h_3) + (h_3 - h_{3s}) + (h_{3s} - h_{3ss})]. \quad (4.16)$$

Now the slope of a constant pressure line on a Mollier diagram is $(\partial h / \partial s)_p = T$, obtained from eqn. (1.28). Thus, for a finite change of enthalpy in a constant pressure process, $\Delta h \cong T \Delta s$ and, therefore,

$$h_{3s} - h_{3ss} \cong T_3 (s_{3s} - s_{3ss}), \quad (4.17a)$$

$$h_2 - h_{2s} \cong T_2 (s_2 - s_{2s}). \quad (4.17b)$$

Noting, from Figure 4.1, that $s_{3s} - s_{3ss} = s_2 - s_{2s}$, the last two equations can be combined to give

$$h_{3s} - h_{3ss} = (T_3/T_2)(h_2 - h_{2s}). \quad (4.18)$$

The effects of irreversibility through the stator and rotor are expressed by the differences in static enthalpies, $(h_2 - h_{2s})$ and $(h_3 - h_{3s})$, respectively. Non-dimensional enthalpy “loss” coefficients can be defined in terms of the exit kinetic energy from each blade row. Thus, for the nozzle row,

$$h_2 - h_{2s} = \frac{1}{2} c_2^2 \zeta_N. \quad (4.19a)$$

For the rotor row,

$$h_3 - h_{3s} = \frac{1}{2} w_3^2 \zeta_R. \quad (4.19b)$$

Combining eqns. (4.19a) and (4.19b) with eqn. (4.16) gives

$$\eta_{tt} = \left[1 + \frac{\zeta_R w_3^2 + \zeta_N c_2^2 T_3/T_2}{2(h_1 - h_3)} \right]^{-1}. \quad (4.20a)$$

When the exit velocity is not recovered (in Chapter 1, examples of such cases are quoted) a total-to-static efficiency for the stage is used:

$$\eta_{ts} = (h_{01} - h_{03})/(h_{01} - h_{3ss}) = \left[1 + \frac{\zeta_R w_3^2 + \zeta_N c_2^2 T_3/T_2 + c_1^2}{2(h_1 - h_3)} \right]^{-1}, \quad (4.21a)$$

where, as before, it is assumed that $c_1 = c_3$.

In initial calculations or in cases where the static temperature drop through the rotor is not large, the temperature ratio T_3/T_2 is set equal to unity, resulting in the more convenient approximations:

$$\eta_{tt} = \left[1 + \frac{\zeta_R w_3^2 + \zeta_N c_2^2}{2(h_1 - h_3)} \right]^{-1}, \quad (4.20b)$$

$$\eta_{ts} = \left[1 + \frac{\zeta_R w_3^2 + \zeta_N c_2^2 + c_1^2}{2(h_1 - h_3)} \right]^{-1}. \quad (4.21b)$$

So that estimates can be made of the efficiency of a proposed turbine stage as part of the preliminary design process, some means of determining the loss coefficients is required. Several methods for doing this are available with varying degrees of complexity. The blade row method proposed by Soderberg (1949) and reported by Horlock (1966), although old, is still useful despite its simplicity. Ainley and Mathieson (1951) correlated the profile loss coefficients for nozzle blades (which give 100% expansion) and impulse blades (which give 0% expansion) against flow deflection and pitch–chord ratio for stated values of Reynolds number and Mach number. Details of their method are given in Chapter 3. For blading between impulse and reaction the profile loss is derived from a combination of the impulse and reaction profile losses (see eqn. 3.49). Horlock (1966) has given a detailed comparison between these two methods of loss prediction. A refinement of the Ainley and Mathieson prediction method was later reported by Dunham and Came (1970).

It should be remembered that loss coefficients based on cascade testing represent only the two-dimensional loss of the aerofoils and in a real turbine various three-dimensional effects also contribute to the loss. These three-dimensional effects include the tip leakage jet, the mixing of any coolant flows and the secondary flows on the turbine end walls. These effects are significant and can contribute more than 50% of the total losses. A description of the various loss mechanisms in turbomachines is given by Denton (1993). This details how the various flow features in a turbine lead to loss sources that can be quantified. Of course, all these losses can be crudely accounted for within a single blade-row loss coefficient, as used in mean-line analysis, but it is very difficult to accurately determine the value required. In many cases, values derived from testing a similar machine are used initially then later refined.

Further preliminary methods of predicting the efficiency of axial flow turbines have been devised, such as those of Craig and Cox (1971), Kacker and Okapuu (1982), and Wilson (1987). Also various proprietary methods are used within industry that are generally semi-empirical methods based on previous test results for turbine stages of a similar design. In addition, computational fluid dynamics can be used to estimate efficiency. However, although CFD can often accurately predict trends in efficiency, absolute performance levels are elusive even with the latest three-dimensional methods. In addition, CFD can be applied only once, detailed turbine rotor and stator geometries have been created. It is therefore more applicable later in the design process (see Chapter 6). Wilson, tellingly, remarked that despite the emergence of “computer programs of great power and sophistication,” these have not yet replaced the preliminary design methods. It is, clearly, essential for a design to converge as closely as possible to an optimum configuration using preliminary design methods before carrying out the final design refinements using computational fluid dynamics.

4.7 PRELIMINARY AXIAL TURBINE DESIGN

The process of choosing the best turbine design for a given application involves juggling several parameters that may be of equal importance, for instance, rotor stress, weight, outside diameter, efficiency, noise, durability, and cost, so that the final design lies within acceptable limits for each parameter. In consequence, a simple presentation can hardly do justice to the real problem of an integrated turbine design. However, a consideration of how the preliminary design choices affect the turbine basic layout and the efficiency can provide useful guidance to the designer.

As demonstrated earlier in the chapter, the main goal in the preliminary stage design of a turbine is to fix the shapes of the velocity triangles, either by setting the flow angles or by choosing values for the three dimensionless design parameters, ϕ , ψ , and R . If we now consider matching the overall (dimensioned) requirements of the turbine to the velocity triangle parameters, the general layout of the turbo-machine can also be determined.

Number of Stages

Firstly, from the specification of the turbine, the design will usually have a known mass flow rate of the working fluid and a required power output. This enables the specific work output of the turbine to be calculated according to $\Delta W = \dot{W}/\dot{m}$. The specific work per stage can be determined from the stage loading and the blade speed and, thus, the required number of stages can be found:

$$n_{\text{stage}} \geq \frac{\dot{W}}{\dot{m}\psi U^2}. \quad (4.22)$$

An inequality is used in eqn. (4.22) since the number of stages must be an integer value. The result shows how a large stage loading can reduce the number of stages required in a multi-stage turbine. It also shows that a high blade speed, U , is desirable. However, this is usually constrained by a stress limit, because centripetal loadings and vibration rise rapidly with rotor speed (see later in this chapter). In some cases aerodynamic or acoustic considerations may limit the maximum blade speed. For example, if a turbine is required to operate with transonic flow, the blade speed may be constrained by the need to limit the maximum flow Mach number.

Blade Height and Mean Radius

Given that the axial velocity remains constant throughout each stage, i.e., $c_{x1} = c_{x2} = c_{x3} = c_x$, then the continuity equation for the turbine reduces to

$$\rho_1 A_{x1} = \rho_2 A_{x2} = \rho_3 A_{x3} = \text{constant.} \quad (4.23)$$

If the mass flow rate through the machine is specified the annulus area, A_x , can be determined from the continuity equation combined with the flow coefficient:

$$A_x = \frac{\dot{m}}{\rho \phi U} \approx 2\pi \times r_m H. \quad (4.24)$$

This equation is only approximate since it assumes the mean radius is exactly midway between the hub and tip, i.e., $r_m = (r_t + r_h)/2$. To be precise, the mean radius should be the radius that divides the annulus into two equal areas, i.e., $r_m^2 = (r_t^2 + r_h^2)/2$. However, for high hub-to-tip radius ratios these definitions of mean radius are equivalent. In all cases, an accurate expression for the annulus area is given by

$$A_x = \pi \times r_t^2 [1 - (r_h/r_t)^2]. \quad (4.25)$$

This equation is useful for determining the annulus area if the hub-to-tip radius ratio required for the turbine is known or if the casing diameter is set by the need to fit the machine in with other components.

Often, the mean radius will be fixed by the need to rotate at a particular rotational speed (e.g., for mains electricity, $\Omega = 50 \text{ Hz} = 3000 \text{ rpm}$) and using a known blade speed, $r_m = U/\Omega$. The spanwise height required for the blades can then be determined from

$$r_t - r_h = H \approx \frac{\dot{m}}{\rho \phi U 2\pi \times r_m}. \quad (4.26)$$

In compressible flow machines, the inlet stagnation conditions and the inlet axial Mach number may be known. This then fixes the inlet annulus area via the mass flow function:

$$\frac{\dot{m} \sqrt{c_p T_{01}}}{A_x \cos \alpha_1} = Q(M_1). \quad (4.27)$$

The area found from this can then be used with eqn. (4.24) or (4.25) to find the blade span. For the subsequent, downstream stage, the stagnation temperature and pressure can be found from the following relationship for the stage loading and pressure ratio:

$$\frac{T_{03}}{T_{01}} = 1 - \frac{\psi U^2}{C_p T_{01}}, \quad \frac{p_{03}}{p_{01}} = \left(\frac{T_{03}}{T_{01}} \right)^{\eta_p \gamma / (\gamma - 1)}. \quad (4.28)$$

Note that the polytropic efficiency is used here since this is more appropriate for calculating changes in properties across a single stage. The Mach number at inlet to the downstream stage can then be found from the velocity using the following compressible flow relationship (included in the compressible flow tables):

$$\frac{c_3}{\sqrt{C_p T_{03}}} = M_3 \sqrt{\gamma - 1} \left(1 + \frac{\gamma - 1}{2} M_3^2 \right)^{-1/2}. \quad (4.29)$$

The new annulus area is then determined from eqn. (4.27) and, given the fact that the mean radius is constant, the blade span can be found. This process can be repeated for subsequent stages, enabling the general arrangement of the entire turbine to be determined in terms of the size and number of stages.

Number of Aerofoils and Axial Chord

The number of aerofoils in each turbine row and the chord lengths of the vanes and blades can also be estimated during the preliminary design. The aspect ratio of a blade row is the height, or blade span, divided by the axial chord, H/b . A suitable value of this is set by mechanical and manufacturing considerations and will vary between applications. For jet engine core turbines aspect ratios between 1 and 2 are usual, but low pressure turbines and steam turbines can have much higher values, as demonstrated in Figures 4.1 and 4.2. To find the ratio of blade pitch to axial chord, s/b , the Zweifel criterion for blade loading can be applied, as detailed in Chapter 3. Equations (3.55) and (3.56) show how, given the turbine velocity triangles, the pitch to axial chord ratio can be found from an optimum value of Zweifel coefficient. For a known axial chord, knowing s/b fixes the number of aerofoils.

4.8 STYLES OF TURBINE

Often, if the stage loading and flow coefficient are fixed by the overall requirements of the turbine and the principal design constraints, only one parameter remains that the designer has the freedom to change in the preliminary design. The classification of different styles of turbine design is most conveniently described by the reaction, because this relates to the turbine blade geometries. There are two extremes: zero reaction, where the rotor and stator shapes are very different, and 50% reaction, where the rotor and stator shapes are symmetric. The advantages and disadvantages of both these styles are discussed next.

Zero Reaction Stage

Walker and Hesketh (1999) summarise the advantages of low reaction as enabling a high stage loading with low interstage swirl, low thrust on the rotor, robust rotor blades, and lower tip leakage flows (due to a low pressure drop across the rotor). However, they also point out that low reaction can lead to boundary layer separation from the highly cambered rotor blades and they show how the increased stage loading almost invariably leads to lower efficiency. Low reaction designs are therefore most advantageous where the need to minimize the number of stages is critical.

**FIGURE 4.6**

Velocity Diagram and Mollier Diagram for a Zero Reaction Turbine Stage

From the definition of reaction, when $R=0$, eqn. (4.2) indicates that $h_2 = h_3$ and, thus, all the enthalpy drop occurs across the stator. From eqn. (4.13b) we can show that

$$R = \frac{\phi}{2} (\tan \beta_3 - \tan \beta_2) \Rightarrow \beta_2 = \beta_3.$$

Since the axial velocity is constant, this means that the relative speed of the flow across the rotor does not change. The Mollier diagram and velocity triangles corresponding to these conditions are sketched in Figure 4.6. From this it is also clear that, since $h_{02rel} = h_{03rel}$ and $h_2 = h_3$ for $R=0$, it follows that $w_2 = w_3$. It will be observed in Figure 4.7 that, because of irreversibility, there is a *pressure drop* through the rotor row. The zero reaction stage is *not* the same thing as an *impulse* stage; in the latter case there is, by definition, no pressure drop through the rotor. The Mollier diagram for an impulse stage is shown in Figure 4.7 where it is seen that the enthalpy *increases* through the rotor. The implication is clear from eqn. (4.3): the reaction is negative for the impulse turbine stage when account is taken of the irreversibility.

50% Reaction Stage

Havakechian and Greim (1999) summarise the advantages of 50% reaction designs as symmetrical velocity triangles leading to similar blade shapes and reduced cost, low turning and highly accelerating passages leading to lower losses, an expansion split into two steps leading to subsonic Mach numbers and improved performance over a range of operating conditions. However, they concede that 50% reaction designs lead to increased turbine part count relative to low reaction designs since roughly twice as many stages are needed, and also the greater expansion through the rotors increases the thrust on the rotors and increases leakage losses.

The symmetrical velocity diagram for this case is shown in Figure 4.8. For $R=0.5$, from eqn. (4.13a) combined with eqn. (4.15), it is found that

$$R = 1 - \frac{\phi}{2} (\tan \alpha_2 - \tan \alpha_1) \Rightarrow 1 = \phi \left(\tan \beta_2 + \frac{1}{\phi} - \tan \alpha_1 \right) \Rightarrow \beta_2 = \alpha_1 = \alpha_3.$$

- (a) Calculate the turbine stage loading coefficient and flow coefficient. Hence, show that the reaction is 0.5 and sketch the velocity triangles for one complete stage.
- (b) Calculate the annulus area at inlet to the turbine. Use this to estimate the blade height and the hub-to-tip radius ratio for the stator in the first turbine stage.

Take $\gamma = 1.333$, $R = 287.2 \text{ J kg}^{-1} \text{ K}^{-1}$, and $c_p = 1150 \text{ J kg}^{-1} \text{ K}^{-1}$ for the gas flowing through both designs of turbine.

Solution

- (a) The mean blade speed can be calculated from the mean radius and angular speed:

$$U = r_m \Omega = 0.46 \times \frac{5600}{60} \times 2\pi = 269.8 \text{ m/s.}$$

The stage loading can then be determined from the power and mass flow:

$$\psi = \frac{\Delta h_0}{U^2} = \frac{\text{Power}/(\dot{m} \times n_{\text{stage}})}{U^2} = \frac{6.64 \times 10^6}{15 \times 5 \times 269.8^2} = 1.217.$$

The flow coefficient follows from eqn. (4.12):

$$\phi = \frac{\psi}{(\tan \alpha_2 + \tan \alpha_1)} = \frac{1.217}{(\tan 70^\circ + \tan 15^\circ)} = 0.403.$$

The reaction can then be determined by rearranging eqn. (4.14):

$$R = 1 - \frac{\psi}{2} + \phi \tan \alpha_1 = 1 - \frac{1.217}{2} + 0.4 \tan 15^\circ = 0.5.$$

Velocity triangles (symmetrical, since $R = 0.5$) are as follows:

- (b) To calculate the inlet area, we first determine the axial Mach number from the inlet axial velocity then use the compressible mass flow function:

$$\frac{c_{1x}}{\sqrt{c_p T_{01}}} = \frac{\phi U}{\sqrt{c_p T_{01}}} = \frac{0.403 \times 269.8}{\sqrt{1150 \times 1200}} = 0.09266.$$

From compressible flow tables ($\gamma = 1.333$), which implies that $M_{1x} = 0.161$, $(\dot{m} \sqrt{c_p T_{01}}) / A_x p_{01} = Q(0.161) = 0.3663$. Therefore,

$$A_x = \frac{\dot{m} \sqrt{c_p T_{01}}}{Q(0.161) p_{01}} = \frac{15 \sqrt{1150 \cdot 1200}}{0.3663 \cdot 213 \times 10^3} = \underline{0.226 \text{ m}^2}.$$

In this case, given the low inlet Mach number, it would also be valid to calculate the density using the inlet stagnation pressure and temperature then apply the continuity equation (4.24). Once the area is found, the blade height and hub-to-tip radius ratio can be determined. For the blade height,

$$H = \frac{A_x}{2\pi r_m} = \frac{0.226}{2\pi \times 0.46} = 0.0782,$$

which implies that $H = 78.2$ mm. For the hub-to-tip ratio,

$$\text{HTR} = \frac{r_m - H/2}{r_m + H/2} = \frac{0.46 - 0.0782/2}{0.46 + 0.0782/2} = \underline{0.843}.$$

4.9 EFFECT OF REACTION ON EFFICIENCY

Consider the problem of selecting an axial turbine design for which the mean blade speed U , the stage loading, ψ (or $\Delta W/U^2$), and the flow coefficient ϕ (or c_x/U) have already been selected. The only remaining parameter required to completely define the velocity triangles is R or the inter-stage swirl angle, α_I , since from eqn. (4.14),

$$\psi = 2(1 - R + \phi \tan \alpha_1).$$

For different values of R the velocity triangles can be constructed, the loss coefficients determined and η_m , η_{ts} calculated. In Shapiro et al. (1957) Stenning considered a family of turbines each having a flow coefficient $c_x/U = 0.4$, blade aspect ratio $H/b = 3$, and Reynolds number $\text{Re} = 10^5$, and calculated η_m , η_{ts} for stage loading factors $\Delta W/U^2$ of 1, 2, and 3 using Soderberg's correlation. The results of this calculation are shown in Figure 4.9 as presented by Shapiro et al. (1957).

In the case of total-to-static efficiency, it is at once apparent that this is optimised, at a given blade loading, by a suitable choice of reaction. When $\Delta W/U^2 = 2$, the maximum value of η_{ts} occurs with approximately zero reaction. With lighter blade loading, the optimum η_{ts} is obtained with higher reaction ratios. When $\Delta W/U^2 > 2$, the highest value of η_{ts} attainable without rotor *relative* flow diffusion occurring, is obtained with $R = 0$. Note that these results relate only to the blading efficiency and make no allowance for losses due to tip clearance and disc friction.

**FIGURE 4.9**

Influence of Reaction on Total-to-Static Efficiency with Fixed Values of Stage Loading Factor

Example 4.2

Verify that the peak value of the total-to-static efficiency η_{ts} , shown in Figure 4.9 occurs at a reaction of 50% for the curve marked $\Delta W/U^2 = 1$ and determine its value. Apply Soderberg's correlation and the data used by Stenning in Shapiro et al. (1957).

Solution

From eqn. (4.21a),

$$\frac{1}{\eta_{ts}} = 1 + \frac{\zeta_R w_3^2 + \zeta_N c_2^2 + c_1^2}{2\Delta W}.$$

As $\Delta W/U^2 = 1$ and $R = 0.5$, from $\psi = 2(1 - R + \phi \tan \alpha_1)$, $\alpha_1 = 0$ and from eqn. (4.15),

$$\tan \beta_3 = \frac{1}{\phi} = 2.5, \text{ and therefore, } \beta_3 = 68.2^\circ.$$

The velocity triangles are symmetrical, so that $\alpha_2 = \beta_3$. Also, $\theta_R = \theta_N = \alpha_2 = 68.2^\circ$; therefore

$$\zeta = 0.04 \times (1 + 1.5 \times 0.682^2) = 0.0679,$$

$$\begin{aligned} \frac{1}{\eta_{ts}} &= 1 + \frac{2\zeta w_3^2 + c_x^2}{2U^2} = 1 + \zeta \phi^2 \sec^2 \beta_3 + \frac{1}{2} \phi^2 \\ &= 1 + \phi^2 (\zeta \sec^2 \beta_3 + 0.5) \\ &= 1 + 0.4^2 \times (0.0679 \times 2.6928^2 + 0.5) \\ &= 1 + 0.16 \times (0.49235 + 0.5), \end{aligned}$$

Therefore,

$$\eta_{ts} = \underline{0.863}.$$

This value appears to be close to the peak value of the efficiency curve $\Delta W/U^2 = 1.0$, in Figure 4.9. Note that it is almost expected that the peak total-to-static efficiency would be at a reaction of 50% for a stage loading of 1, because this is where there is no inter-stage swirl; and thus for a fixed axial velocity, the exit kinetic energy will be minimised. If the total-to-total efficiency was considered, this would not be greatly affected by the choice of reaction. However, the maximum value of η_{tt} is found, in general, to decrease slightly as the stage loading factor increases (see Section 4.12).

4.10 DIFFUSION WITHIN BLADE ROWS

Any diffusion of the flow through turbine blade rows is particularly undesirable and must, at the design stage, be avoided at all costs. This is because the adverse pressure gradient (arising from the flow diffusion), coupled with large amounts of fluid deflection (usual in turbine blade rows), makes boundary-layer separation more than merely possible, with the result that large scale losses arise. A compressor blade row, on the other hand, is designed to cause the fluid pressure to rise in the direction of flow, i.e., an *adverse* pressure gradient. The magnitude of this gradient is strictly controlled in a compressor, mainly by having a fairly limited amount of fluid deflection in each blade row.

It was shown previously that negative values of reaction indicated diffusion of the rotor relative velocity (i.e., for $R < 0$, $w_3 < w_2$). A similar condition that holds for diffusion of the nozzle absolute velocity is that, if $R > 1$, $c_2 < c_1$.

If we consider eqn. (4.13), this can be written as

$$R = 1 + \frac{\phi}{2} (\tan \alpha_3 - \tan \alpha_2).$$

Thus, when $\alpha_3 = \alpha_2$ the reaction is unity (also $c_2 = c_3$). The velocity diagram for $R = 1$ is shown in Figure 4.10 with the same values of c_x , U , and ΔW used for $R = 0$ and $R = \frac{1}{2}$. It will be apparent that, if R exceeds unity, then $c_2 < c_1$ (i.e., nozzle flow *diffusion*).

Example 4.3

A single-stage gas turbine operates at its design condition with an axial absolute flow at entry and exit from the stage. The absolute flow angle at nozzle exit is 70° . At stage entry the total pressure and temperature are 311 kPa and 850°C ,

FIGURE 4.10

Velocity Diagram for 100% Reaction Turbine Stage

respectively. The exhaust static pressure is 100 kPa, the total-to-static efficiency is 0.87, and the mean blade speed is 500 m/s.

Assuming constant axial velocity through the stage, determine

- (i) the specific work done;
- (ii) the Mach number leaving the nozzle;
- (iii) the axial velocity;
- (iv) the total-to-total efficiency;
- (v) the stage reaction.

Take $C_p = 1.148 \text{ kJ/(kg}^\circ\text{C)}$ and $\gamma = 1.33$ for the gas.

Solution

- (i) From eqn. (4.10), total-to-static efficiency is

$$\eta_{ts} = \frac{h_{01} - h_{03}}{h_{01} - h_{3ss}} = \frac{\Delta W}{h_{01} [1 - (p_3/p_{01})^{(\gamma-1)/\gamma}]}$$

Thus, the specific work is

$$\begin{aligned} \Delta W &= \eta_{ts} C_p T_{01} [1 - (p_3/p_{01})^{(\gamma-1)/\gamma}] \\ &= 0.87 \times 1148 \times 1123 \times [1 - (1/3.11)^{0.248}] \\ &= 276 \text{ kJ/kg.} \end{aligned}$$

- (ii) At nozzle exit the Mach number is

$$M_2 = c_2 / (\gamma R T_2)^{1/2},$$

and it is necessary to solve the velocity diagram to find c_2 and, hence, to determine T_2 . As

$$c_{\theta 3} = 0, \Delta W = U c_{\theta 2},$$

$$c_{\theta 2} = \frac{\Delta W}{U} = \frac{276 \times 10^3}{500} = 552 \text{ m/s,}$$

$$c_2 = c_{\theta 2} / \sin \alpha_2 = 588 \text{ m/s.}$$

Referring to Figure 4.1, across the nozzle $h_{01} = h_{02} = h_2 + \frac{1}{2} c_2^2$, thus,

$$T_2 = T_{01} - \frac{1}{2} c_2^2 / C_p = 973 \text{ K.}$$

Hence, $M_2 = 0.97$ with $\gamma R = (\gamma - 1) C_p$.

- (iii) The axial velocity, $c_x = c_2 \cos \alpha_2 = 200 \text{ m/s.}$

- (iv) $\eta_{tt} = \Delta W / (h_{01} + h_{3ss} - \frac{1}{2} c_3^2)$.

After some rearrangement,

$$\frac{1}{\eta_{tt}} = \frac{1}{\eta_{ts}} - \frac{c_3^2}{2\Delta W} = \frac{1}{0.87} - \frac{200^2}{2 \times 276 \times 10^3} = 1.0775.$$

Therefore, $\eta_{tt} = 0.93$.

(v) Using eqn. (4.13b), the reaction is

$$R = \frac{1}{2}(c_x/U)(\tan \beta_3 - \tan \beta_2).$$

From the velocity diagram, $\tan \beta_3 = U/c_x$ and $\tan \beta_2 = \tan \alpha_2 - U/c_x$

$$R = 1 - \frac{1}{2}(c_x/U) \tan \alpha_2 = 1 - 200 \times 0.2745/1000 = 0.451.$$

Example 4.4

Verify the assumed value of total-to-static efficiency in the preceding example using Soderberg's correlation method. The average blade aspect ratio for the stage $H/b = 5.0$, the maximum blade thickness–chord ratio is 0.2, and the average Reynolds number is 10^5 .

Solution

The approximation for total-to-static efficiency, eqn. (4.21b), is used and can be rewritten as

$$\frac{1}{\eta_{ts}} = 1 + \frac{\zeta_R(w_3/U)^2 + \zeta_N(c_2/U)^2 + (c_x/U)^2}{2\Delta W/U^2}.$$

The loss coefficients ζ_R and ζ_N , uncorrected for the effects of blade aspect ratio, are determined using eqn. (3.50), which requires a knowledge of flow turning angle θ for each blade row.

For the nozzles, $\alpha_1 = 0$ and $\alpha_2 = 70^\circ$, thus $\theta_N = 70^\circ$:

$$\zeta_N^* = 0.04(1 + 1.5 \times 0.7^2) = 0.0694.$$

Correcting for the aspect ratio with eqn. (3.51a),

$$\zeta_{N1} = 1.0694(0.993 + 0.021/5) - 1 = 0.0666.$$

For the rotor, $\tan \beta_2 = (c_{\theta 2} - U)/c_x = (552 - 500)/200 = 0.26$; therefore,

$$\beta_2 = 14.55^\circ.$$

Therefore,

$$\tan \beta_3 = U/c_x = 2.5,$$

and

$$\beta_3 = 68.2^\circ.$$

Therefore,

$$\varepsilon_R = \beta_2 + \beta_3 = 82.75^\circ,$$

$$\zeta_R^* = 0.04(1 + 1.5 \times 0.8275^2) = 0.0812.$$

Correcting for the aspect ratio with eqn. (3.51b)

$$\zeta_{R1} = 1.0812(0.975 + 0.075/5) - 1 = 0.0712.$$

The velocity ratios are

$$\left(\frac{w_3}{U}\right)^2 = 1 + \left(\frac{c_x}{U}\right)^2 = 1.16,$$

$$\left(\frac{c_2}{U}\right)^2 = \left(\frac{588}{500}\right)^2 = 1.382; \left(\frac{c_x}{U}\right)^2 = 0.16$$

and the stage loading factor is

$$\frac{\Delta W}{U^2} = \frac{c_{\theta 2}}{U} = \frac{552}{500} = 1.104.$$

Therefore,

$$\frac{1}{\eta_{ts}} = 1 + \frac{0.0712 \times 1.16 + 0.0666 \times 1.382 + 0.16}{2 \times 1.104} = 1 + 0.1515$$

and

$$\eta_{ts} = 0.869.$$

This result is very close to the value assumed in the first example.

It is not too difficult to include the temperature ratio T_3/T_2 implicit in the more exact eqn. (4.21a) to see how little effect the correction will have. To calculate T_3 ,

$$T_3 = T_{01} - \frac{\Delta W + \frac{1}{2}c_3^2}{C_p} = 1123 - \frac{276,000 + 20,000}{1148} = 865 \text{ K.}$$

$$T_3/T_2 = 865/973 = 0.89.$$

Therefore,

$$\frac{1}{\eta_{ts}} = 1 + \frac{0.0712 \times 1.16 + 0.89 \times 0.0666 \times 1.382 + 0.16}{2 \times 1.104} = 1 + 0.14168,$$

and

$$\eta_{ts} = 0.872.$$

4.11 THE EFFICIENCY CORRELATION OF SMITH (1965)

All manufacturers of steam and gas turbines keep large databases of measured efficiency of axial-flow turbine stages as functions of the duty parameters (flow coefficient, ϕ , and stage loading coefficient, ψ). Smith (1965), devised a widely used efficiency correlation, based upon data obtained from 70 Rolls-Royce aircraft gas turbines, such as the Avon, Dart, Spey, Conway, and others, including the special four-stage turbine test facility at Rolls-Royce, Derby, England. The data points and efficiency curves found by him are shown in Figure 4.11. It is worth knowing that all stages tested were constant axial velocity, the reactions were between 0.2 and 0.6 and the blade aspect ratio (blade height to chord ratio) was relatively large, between 3 and 4. Another important factor to remember was that all

**FIGURE 4.11**

Smith Chart for Turbine Stage Efficiency (Smith, 1965, with Permission from the Royal Aeronautical Society and its Aeronautical Journal)

efficiencies were corrected to eliminate tip leakage loss so that, in actual operation, the efficiencies would be higher than those expected for the equivalent real turbines. The tip leakage losses (which can be very large) were found by repeating tests with different amounts of tip clearance and extrapolating the results back to zero clearance to get the desired result.

Every turbine was tested over a range of pressure ratios to find its point of maximum efficiency and to determine the corresponding values of ψ and ϕ . Each point plotted in Figure 4.11 represents just one test turbine at its best efficiency point and the value of its efficiency is shown adjacent to that point. Confirmatory tests made by Kacker and Okapuu (1982) and others have shown the usefulness of the chart in preliminary turbine design.

**FIGURE 4.12**

Dimensionless Velocity Triangles for a 50% Reaction Turbine Stage

Smith developed a simple theoretical analysis to explain the shape of the efficiency curves. He argued that the losses in any blade row were proportional to the average absolute kinetic energy, $\frac{1}{2}(c_1^2 + c_2^2)$, for that row. For $R = 0.5$, Smith defined a factor f_s as the ratio of the shaft work output to the sum of the mean kinetic energies within the rotor and stator. Thus,

$$f_s = \Delta h_0 / (c_1^2 + c_2^2) = \frac{\Delta h_0 / U^2}{(c_1^2 / U^2) + (c_2^2 / U^2)}. \quad (4.30)$$

Following the reasoning of Smith it is helpful to non-dimensionalise the velocity triangles for the complete stage, assuming $R = 0.5$, as shown in Figure 4.12. It will be observed that $\tan \alpha_1 = \tan \beta_2 = (\psi - 1) / 2\phi$ and $\tan \alpha_2 = \tan \beta_3 = (\psi + 1) / 2\phi$. Solving for the non-dimensionalised velocities in terms of ψ and ϕ we find

$$\frac{c_2}{U} = \frac{w_3}{U} = \sqrt{\phi^2 + \left(\frac{\psi + 1}{2}\right)^2}$$

and

$$\frac{c_1}{U} = \frac{w_2}{U} = \sqrt{\phi^2 + \left(\frac{\psi - 1}{2}\right)^2}.$$

Substituting into eqn. (4.30), we obtain

$$f_s = \frac{\psi}{\phi^2 + \left(\frac{\psi+1}{2}\right)^2 + \phi^2 + \left(\frac{\psi-1}{2}\right)^2} = \frac{2\psi}{4\phi^2 + \psi^2 + 1}. \quad (4.31)$$

From this expression the optimum stage work coefficient, ψ , for a given flow coefficient, ϕ , can be found by differentiating with respect to ψ :

$$\frac{\partial f_s}{\partial \psi} = \frac{2(4\phi^2 - \psi^2 + 1)}{(4\phi^2 + \psi^2 + 1)} = 0.$$

FIGURE 4.13

Smith's Kinetic Energy Coefficient f_s and the Optimum Stage Loading, ψ_{opt} , Plotted against the Stage Loading Coefficient and Flow Coefficient for a Turbine Stage

From this expression the optimum curve is easily derived:

$$\psi_{\text{opt}} = \sqrt{4\phi^2 + 1}. \quad (4.32)$$

Figure 4.13 is a carpet plot of ψ versus ϕ for various values of f_s . Superimposed on this plot is the locus of the optimum curve defined by eqn. (4.32). It has been noted that this curve tends to follow the trend of the optimum efficiency of the Rolls-Royce efficiency correlation given in Figure 4.13. It has been reported by Lewis (1996) that a more accurate representation of the optimum can be picked out from the Rolls-Royce data as

$$\psi_{\text{opt.exp}} = 0.65\sqrt{4\phi^2 + 1}. \quad (4.33)$$

It is worth knowing that Lewis (1996) developed Smith's method of analysis to include the blade aerodynamics and blade loss coefficients adding further insight into the method.

4.12 DESIGN POINT EFFICIENCY OF A TURBINE STAGE

The performance of a turbine stage in terms of its efficiency is calculated for several types of design, i.e., 50% reaction, zero reaction, and zero exit flow angle, using the loss correlation method of Soderberg described earlier. These are most usefully presented in the form of carpet plots of the stage loading coefficient, ψ , and flow coefficient, ϕ .

Total-to-Total Efficiency of 50% Reaction Stage

In a multi-stage turbine the total-to-total efficiency is the relevant performance criterion, the kinetic energy at stage exit being recovered in the next stage. After the last stage of a multi-stage turbine

or a single stage turbine, the kinetic energy in the exit flow would be recovered in a diffuser or used for another purpose (e.g., as a contribution to the propulsive thrust).

From eqn. (4.20b), where it has already been assumed that $c_1 = c_3$ and $T_3 = T_2$, we have

$$\frac{1}{\eta_{tt}} = 1 + \frac{(\zeta_R w_3^2 + \zeta_N c_2^2)}{2\Delta W},$$

where $\Delta W = \psi U^2$ and, for a 50% reaction, $w_3 = c_2$ and $\zeta_R = \zeta_N = \zeta$:

$$w_3^2 = c_x^2 \sec^2 \beta_3 = c_x^2 (1 + \tan^2 \beta_3).$$

Therefore,

$$\frac{1}{\eta_{tt}} = 1 + \frac{\zeta \phi^2}{\psi} (1 + \tan^2 \beta_3) = 1 + \frac{\zeta \phi^2}{\psi} \left[1 + \left(\frac{1 + \psi}{2\phi} \right)^2 \right].$$

as $\tan \beta_3 = (\psi + 1)/(2\phi)$ and $\tan \beta_2 = (\psi - 1)/(2\phi)$.

From these expressions the performance chart, shown in Figure 4.14, was derived for specified values of ψ and ϕ . From this chart it can be seen that the peak total-to-total efficiency, η_{tt} , is obtained at very low values of ϕ and ψ . As indicated in a survey by Kacker and Okapuu (1982), most aircraft gas turbine designs will operate with flow coefficients in the range, $0.5 \leq \phi \leq 1.5$, and values of stage loading coefficient in the range, $0.8 \leq \psi \leq 2.8$.

FIGURE 4.14

Design Point Total-to-Total Efficiency and Deflection Angle Contours for a Turbine Stage of 50% Reaction

Total-to-Total Efficiency of a Zero Reaction Stage

The degree of reaction will normally vary along the length of the blade depending upon the type of design specified. The performance for $R=0$ represents a limit, lower values of reaction are possible but undesirable as they would give rise to large losses in efficiency. For $R < 0$, $w_3 < w_2$, which means the relative flow decelerates across the rotor.

Referring to Figure 4.6, for zero reaction $\beta_2 = \beta_3$, and from eqn. (4.15)

$$\tan \alpha_2 = 1/\phi + \tan \beta_2 \text{ and } \tan \alpha_3 = \tan \beta_3 - 1/\phi.$$

Also, $\psi = \Delta W/U^2 = \phi(\tan \alpha_2 + \tan \alpha_3) = \phi(\tan \beta_2 + \tan \beta_3) = 2\phi \tan \beta_2$; therefore,

$$\tan \beta_2 = \frac{\psi}{2\phi}.$$

Thus, using the preceding expressions,

$$\tan \alpha_2 = (\psi/2 + 1)/\phi \text{ and } \tan \alpha_3 = (\psi/2 - 1)/\phi.$$

From these expressions the flow angles can be calculated if values for ψ and ϕ are specified. From an inspection of the velocity diagram,

$$c_2 = c_x \sec \alpha_2, \text{ hence, } c_2^2 = c_x^2(1 + \tan^2 \alpha_2) = c_x^2[1 + (\psi/2 + 1)^2/\phi^2],$$

$$w_3 = c_x \sec \beta_3, \text{ hence, } w_3^2 = c_x^2(1 + \tan^2 \beta_3) = c_x^2[1 + (\psi/2\phi)^2].$$

Substituting these expressions into eqn. (4.20b),

$$\frac{1}{\eta_{tt}} = 1 + \frac{\zeta_R w_3^2 + \zeta_N c_2^2}{2\psi U^2},$$

$$\frac{1}{\eta_{tt}} = 1 + \frac{1}{2\psi} \left\{ \zeta_R \left[\phi^2 + \left(\frac{\psi}{2} \right)^2 \right] + \zeta_N \left[\phi^2 + \left(1 + \frac{\psi}{2} \right)^2 \right] \right\}.$$

The performance chart shown in Figure 4.15 was derived using these expressions. This is similar in its general form to Figure 4.14 for a 50% reaction, with the highest efficiencies being obtained at the lowest values of ϕ and ψ , except that higher efficiencies are obtained at higher values of the stage loading but at reduced values of the flow coefficient.

Total-to-Static Efficiency of Stage with Axial Velocity at Exit

A single stage axial turbine will have axial flow at exit and the most appropriate efficiency is usually total to static. To calculate the performance, eqn. (4.21b) is used:

$$\frac{1}{\eta_{ts}} = 1 + \frac{(\zeta_R w_3^2 + \zeta_N c_2^2 + c_1^2)}{2\Delta W} = 1 + \frac{\phi^2}{2\psi} (\zeta_R \sec^2 \beta_3 + \zeta_N \sec^2 \alpha_2 + 1).$$

FIGURE 4.15

Design Point Total-to-Total Efficiency and Rotor Flow Deflection Angle for a Zero Reaction Turbine Stage

With axial flow at exit, $c_1 = c_3 = c_x$, and from the velocity diagram, Figure 4.16,

$$\tan \beta_3 = U/c_x, \quad \tan \beta_2 = \tan \alpha_2 - \tan \beta_3,$$

$$\sec^2 \beta_3 = 1 + \tan^2 \beta_3 = 1 + 1/\phi^2,$$

$$\sec^2 \alpha_2 = 1 + \tan^2 \alpha_2 = 1 + (\psi/\phi)^2,$$

Therefore,

$$\frac{1}{\eta_{ts}} = 1 + \frac{1}{2\phi} \left[\zeta_R(1 + \phi^2) + \zeta_N(\psi^2 + \phi^2) + \phi^2 \right].$$

Specifying ϕ and ψ , the unknown values of the loss coefficients, ζ_R and ζ_N , can be derived using Soderberg's correlation, eqn. (3.50), in which

$$\varepsilon_N = \alpha_2 = \tan^{-1}(\psi/\phi) \quad \text{and} \quad \varepsilon_R = \beta_2 + \beta_3 = \tan^{-1}(1/\phi) + \tan^{-1}[(\psi - 1)/\phi].$$

From these expressions the performance chart, Figure 4.17, was derived.

An additional limitation is imposed on the performance chart because of the reaction, which must remain greater than or, in the limit, equal to zero. From eqn. (4.14) for zero inter-stage swirl,

$$\psi = 2(1 - R).$$

Thus, at the limit, $R = 0$, and the stage loading coefficient, $\psi = 2$.

**FIGURE 4.16**

Velocity Diagram for a Turbine Stage with Axial Exit Flow

**FIGURE 4.17**

Total-to-Static Efficiency Contours for a Stage with Axial Flow at Exit

4.13 STRESSES IN TURBINE ROTOR BLADES

Although this chapter is primarily concerned with the fluid mechanics and thermodynamics of turbines, some consideration of stresses in rotor blades is needed as these can place restrictions on the allowable blade height and annulus flow area, particularly in high temperature, high stress situations. Only a very brief outline is attempted here of a very large subject, which is treated at much greater length by Horlock (1966), in texts dealing with the mechanics of solids, e.g., Den Hartog (1952), Timoshenko (1956), and in specialised discourses, e.g., Japiske (1986) and Smith (1986). The stresses in turbine

blades arise from centrifugal loads, from gas bending loads and from vibrational effects caused by non-constant gas loads. Although the centrifugal stress produces the biggest contribution to the total stress, the vibrational stress is very significant and thought to be responsible for fairly common vibratory fatigue failures (Smith, 1986). The direct and simple approach to blade vibration is to “tune” the blades so that resonance does not occur in the operating range of the turbine. This means obtaining a blade design in which none of its natural frequencies coincides with any excitation frequency. The subject is complex and interesting, but outside of the scope of the present text.

Centrifugal Stresses

Consider a blade rotating about an axis O as shown in Figure 4.18. For an element of the blade of length dr at radius r , at a rotational speed Ω the elementary centrifugal load dF_c is given by

$$dF_c = -\Omega^2 r dm,$$

FIGURE 4.18

Centrifugal Forces Acting on Rotor Blade Element

where $dm = \rho_m A dr$ and the negative sign accounts for the direction of the stress gradient (i.e., zero stress at the blade tip to a maximum at the blade root),

$$\frac{d\sigma_c}{\rho_m} = \frac{dF_c}{\rho_m A} = -\Omega^2 r dr.$$

For blades with a constant cross-sectional area, we get

$$\frac{\sigma_c}{\rho_m} = \Omega^2 \int_{r_h}^{r_t} r dr = \frac{U_t^2}{2} \left[1 - \left(\frac{r_h}{r_t} \right)^2 \right]. \quad (4.34a)$$

A rotor blade is usually tapered both in chord and in thickness from root to tip, such that the area ratio A_t/A_h is between 1/3 and 1/4. For such a blade taper it is often assumed that the blade stress is reduced to two thirds of the value obtained for an untapered blade. A blade stress taper factor can be defined as

$$K = \frac{\text{stress at root of tapered blade}}{\text{stress at root of untapered blade}}.$$

Thus, for tapered blades

$$\frac{\sigma_c}{\rho_m} = \frac{KU_t^2}{2} \left[1 - \left(\frac{r_h}{r_t} \right)^2 \right]. \quad (4.34b)$$

Values of the taper factor K quoted by Emmert (1950) are shown in Figure 4.19 for various taper geometries.

Typical data for the allowable stresses of commonly used alloys are shown in Figure 4.20 for the “1000 hour rupture life” limit with maximum stress allowed plotted as a function of blade temperature. It can be seen that, in the temperature range 900–1100 K, nickel or cobalt alloys are likely to be suitable and for temperatures up to about 1300 K molybdenum alloys would be needed.

FIGURE 4.19

Effect of Tapering on Centrifugal Stress at Blade Root (Adapted from Emmert, 1950)

**FIGURE 4.20**

Maximum Allowable Stress for Various Alloys (1000 Hour Rupture Life) (Adapted from Freeman, 1955)

Further detailed information on one of the many alloys used for gas turbines blades is shown in Figure 4.21. This material is Inconel, a nickel-based alloy containing 13% chromium, 6% iron, with a little manganese, silicon, and copper. Figure 4.21 shows the influence of the “rupture life” and also the “percentage creep,” which is the elongation strain at the allowable stress and temperature of the blade. To enable operation at high temperatures and for long life of the blades, the creep strength criterion is the one usually applied by designers.

An estimate of the average rotor blade temperature T_b can be made using the approximation

$$T_b = T_2 + 0.85 w_2^2 / (2C_p), \quad (4.35)$$

i.e., 85% temperature recovery of the inlet *relative kinetic energy*.

Example 4.5

Combustion gases enter the first stage of a gas turbine at a stagnation temperature and pressure of 1200 K and 4.0 bar. The rotor blade tip diameter is 0.75 m, the blade height is 0.12 m, and the shaft speed is 10,500 rev/min. At the mean radius the stage operates with a reaction of 50%, a flow coefficient of 0.7, and a stage loading coefficient of 2.5.

Determine

- (i) the relative and absolute flow angles for the stage;
- (ii) the velocity at nozzle exit;
- (iii) the static temperature and pressure at nozzle exit assuming a nozzle efficiency of 0.96 and the mass flow;
- (iv) the rotor blade root stress assuming the blade is tapered with a stress taper factor K of $2/3$ and the blade material density is 8000 kg/m³;

FIGURE 4.21

Properties of Inconel 713 Cast Alloy (Adapted from Balje, 1981)

- (v) the approximate mean blade temperature;
- (vi) taking only the centrifugal stress into account suggest a suitable alloy from the information provided that could be used to withstand 1000 h of operation.

Solution

- (i) The stage loading is

$$\psi = \Delta h_0 / U^2 = (w_{\theta 3} + w_{\theta 2}) / U = \phi (\tan \beta_3 + \tan \beta_2).$$

From eqn. (4.13b) the reaction is

$$R = \phi (\tan \beta_3 - \tan \beta_2) / 2.$$

Adding and subtracting these two expressions, we get

$$\tan \beta_3 = (\psi / 2 + R) / \phi \text{ and } \tan \beta_2 = (\psi / 2 - R) / \phi.$$

Substituting values of ψ , ϕ , and R into the preceding equations, we obtain

$$\beta_3 = 68.2^\circ, \beta_2 = 46.98^\circ,$$

and for similar triangles (i.e., 50% reaction),

$$\alpha_2 = \beta_3 \text{ and } \alpha_3 = \beta_2.$$

- (ii) At the mean radius, $r_m = (0.75 - 0.12)/2 = 0.315$ m, the blade speed is $U_m = \Omega r_m = (10,500/30) \times \pi \times 0.315 = 1099.6 \times 0.315 = 346.36$ m/s. The axial velocity $c_x = \phi U_m = 0.5 \times 346.36 = 242.45$ m/s and the velocity of the gas at nozzle exit is $c_2 = c_x / \cos \alpha_2 = 242.45 / \cos 68.2 = 652.86$ m/s.
- (iii) To determine the conditions at nozzle exit, we have

$$T_2 = T_{02} - \frac{1}{2} c_2^2 / C_p = 1200 - 652.86^2 / (2 \times 1160) = 1016.3 \text{ K}.$$

The nozzle efficiency is

$$\eta_N = \frac{h_{01} - h_2}{h_{01} - h_{2s}} = \frac{1 - T_2/T_{01}}{1 - (p_2/p_{01})^{(\gamma-1)/\gamma}},$$

Therefore,

$$\left(\frac{p_2}{p_{01}} \right)^{(\gamma-1)/\gamma} = 1 - \frac{1 - T_2/T_{01}}{\eta_N} = 1 - (1 - 1016.3/1200)/0.96 = 0.84052$$

and

$$p_2 = 4 \times 0.84052^{4.0303} = 1.986 \text{ bar}.$$

The mass flow is found from the continuity equation:

$$\dot{m} = \rho_2 A_2 c_{x2} = \left(\frac{p_2}{RT_2} \right) A_2 c_{x2};$$

therefore,

$$\dot{m} = \left(\frac{1.986 \times 10^5}{287.8 \times 1016.3} \right) \times 0.2375 \times 242.45 = 39.1 \text{ kg/s}.$$

- (iv) For a tapered blade, eqn. (4.34b) gives

$$\frac{\sigma_c}{\rho_m} = \frac{2}{3} \times \frac{412.3^2}{2} \left[1 - \left(\frac{0.51}{0.75} \right)^2 \right] = 30463.5 \text{ m}^2/\text{s}^2,$$

where $U_t = 1099.6 \times 0.375 = 412.3$ m/s.

The density of the blade material is taken to be 8000 kg/m^3 and so the root stress is

$$\sigma_c = 8000 \times 30463.5 = 2.437 \times 10^8 \text{ N/m}^2 = 243.7 \text{ MPa}.$$

- (v) The approximate average mean blade temperature is

$$T_b = 1016.3 + 0.85 \times (242.45 / \cos 46.975)^2 / (2 \times 1160) = 1016.3 + 46.26 = 1062.6 \text{ K}.$$

- (vi) The data in Figure 4.20 suggest that, for this moderate root stress, cobalt or nickel alloys would not withstand a lifespan of 1000 h to rupture and the use of molybdenum would be necessary. However, it would be necessary to take account of bending and vibratory stresses and the decision about the choice of a suitable blade material would be decided on the outcome of these calculations.

Inspection of the data for Inconel 713 cast alloy, Figure 4.21, suggests that it might be a better choice of blade material as the temperature–stress point of the preceding calculation is to the left of the line marked creep strain of 0.2% in 1000 h. Again, account must be taken of the additional stresses due to bending and vibration.

Design is a process of trial and error; changes in the values of some of the parameters can lead to a more viable solution. In this case (with bending and vibrational stresses included) it might be necessary to reduce one or more of the values chosen, e.g.,

- the rotational speed;
- the inlet stagnation temperature;
- the flow area.

Note: The combination of values for ψ and ϕ at $R = 0.5$ used in this example was selected from data given by Wilson (1987) and corresponds to an optimum total-to-total efficiency of 91.9%.

4.14 TURBINE BLADE COOLING

In the gas turbine industry there has been a continuing trend towards higher turbine inlet temperatures, to give increased specific thrust (thrust per unit air mass flow) and to allow the specific fuel consumption to be reduced. The highest allowable gas temperature at entry to a turbine with uncooled blades is 1000°C while, with a sophisticated blade cooling system, gas temperatures up to about 1800°C are possible, depending on the nature of the cooling system. Such high temperatures are well in excess of the melting point of the leading nickel-based alloys from which the blades are cast.

Various types of cooling system for gas turbines have been considered in the past and a number of these are now in use. In the Rolls-Royce Trent engines (source, Rolls-Royce (2005)) the HP turbine blades, nozzle guide vanes, and seal segments are cooled internally and externally using cooling air from the final stage of the HP compressor. This cooling air is itself at a temperature of over 700°C and at a pressure of 3.8 MPa. The hot gas stream at the turbine inlet is at a pressure of over 3.6 MPa so the pressure margin is quite small and maintaining that margin is critical to the lifespan of the engine. Figure 4.22 illustrates a high pressure turbine rotor blade, sectioned to show the intricate labyrinth of passages through which the cooling air passes before part of it is vented to the blade surface via the rows of tiny holes along and around the hottest areas of the blade. Ideally, the air emerges with little velocity and forms a film of cool air around the blade surface (hence, the term *film cooling*), insulating it from the hot gases. This type of cooling system enables turbine entry temperatures up to 1800 K to be used. Figure. 4.23 shows the way the cooling air is used to cool HP nozzle guide vanes in a modern jet engine.

A rising thermodynamic penalty is incurred with blade cooling systems as the turbine entry temperature rises, e.g., energy must be supplied to pressurise the air bled off from the compressor. Figure 4.24 is taken from Wilde (1977) showing how the net turbine efficiency decreases with increasing turbine entry temperature. Several in-service gas turbine engines for that era are included in the graph. Wilde did question whether turbine entry temperatures greater than 1330°C could really be justified in turbofan engines because of the effect on the internal aerodynamic efficiency and specific fuel consumption. However, time and experience have since shown the important operational advantage of using blade cooling systems.

Turbine Thermal Efficiency versus Inlet Gas Temperature (Wilde, 1977)

4.15 TURBINE FLOW CHARACTERISTICS

An accurate knowledge of the flow characteristics of a turbine is of considerable practical importance as, for instance, in the matching of flows between a compressor and turbine of a jet engine. Figure 4.25, after Mallinson and Lewis (1948), shows a comparison of typical characteristics for one, two, and three stages plotted as turbine overall pressure ratio p_{0e}/p_{01} against a mass flow coefficient $\dot{m}(\sqrt{T_{01}})/p_{01}$. There is a noticeable tendency for the characteristic to become more ellipsoidal as the number of stages is increased. At a given pressure ratio the mass flow coefficient, or “swallowing capacity,” tends to decrease with the addition of further stages to the turbine. One of the earliest attempts to assess the flow variation of a multi-stage turbine is credited to Stodola (1945), who formulated the much used “ellipse law.” The curve labelled *multi-stage* in Figure 4.25 is in agreement with the “ellipse law” expression

$$\dot{m}(\sqrt{T_{01}})/p_{01} = k[1 - (p_{0e}/p_{01})^2]^{1/2}, \quad (4.36)$$

where k is a constant.

This expression has been used for many years in steam turbine practice, but an accurate estimate of the variation in swallowing capacity with pressure ratio is of even greater importance in gas turbine technology. Whereas, the average condensing steam turbine, even at part-load, operates at very high pressure ratios, some gas turbines may work at rather low pressure ratios, making flow matching with a compressor a more difficult problem.

**FIGURE 4.25**

Turbine Flow Characteristics (after Mallinson and Lewis, 1948)

Note that, when the pressure ratio across a single stage turbine exceeds about 2, the turbine stator blades choke and the flow capacity becomes constant. Beyond this point the turbine behaves much the same as a choked nozzle, and the performance is fairly independent of the turbine rotational speed. For multi-stage turbines the choking pressure ratio increases as more stages are added.

Flow Characteristics of a Multi-stage Turbine

Several derivations of the ellipse law are available in the literature. The derivation given here is a slightly amplified version of the proof given by Horlock (1958). A more general method has been given by Egli (1936), which takes into consideration the effects when operating outside the normal low loss region of the blade rows.

Consider a turbine comprising a large number of normal stages, each of 50% reaction; then, referring to the velocity diagram of Figure 4.26(a), $c_1 = c_3 = w_2$ and $c_2 = w_3$. If the blade speed is maintained constant and the mass flow is reduced, the fluid angles at exit from the rotor (β_3) and nozzles (α_2) will remain constant and the velocity diagram then assumes the form shown in Figure 4.26(b). The turbine, if operated in this manner, will be of low efficiency, as the fluid direction at inlet to each blade row is likely to produce a negative incidence stall. To maintain high efficiency the fluid inlet angles must remain fairly close to the design values. It is therefore assumed that the turbine operates at its highest efficiency at *all off-design conditions* and, by implication, the blade speed is changed in direct proportion to the axial velocity. The velocity triangles are similar at off-design flows but of different scale.

Now the work done by unit mass of fluid through one stage is $U(c_{\theta 2} + c_{\theta 3})$ so that, assuming a perfect gas,

$$C_p \Delta T_0 = C_p \Delta T = U c_x (\tan \alpha_2 + \tan \alpha_3),$$

**FIGURE 4.26**

Change in Turbine Stage Velocity Diagram with Mass Flow at Constant Blade Speed

and therefore,

$$\Delta T \propto c_x^2.$$

Denoting design conditions by subscript d , then

$$\frac{\Delta T}{\Delta T_d} = \left(\frac{c_x}{c_{xd}} \right)^2 \quad (4.37)$$

for equal values of c_x/U .

From the continuity equation, at off-design, $\dot{m} = \rho A_x c_x = \rho_1 A_{x1} c_{x1}$, and at design, $\dot{m}_d = \rho_d A_x c_{xd} = \rho_1 A_{x1} c_{x1}$; hence,

$$\frac{c_x}{c_{xd}} = \frac{\rho_d}{\rho} \frac{c_{x1}}{c_{x1d}} = \frac{\rho_d}{\rho} \frac{\dot{m}}{\dot{m}_d}. \quad (4.38)$$

Consistent with the assumed mode of turbine operation, the polytropic efficiency is taken to be constant at off-design conditions and, from eqn. (1.50), the relationship between temperature and pressure is, therefore,

$$T/p^{\eta_p(\gamma-1)/\gamma} = \text{constant}.$$

Combined with $p/\rho = RT$ the above expression gives, on eliminating p , $\rho/T^n = \text{constant}$, hence,

$$\frac{\rho}{\rho_d} = \left(\frac{T}{T_d} \right)^n, \quad (4.39)$$

where $n = \gamma/[\eta_p(\gamma - 1)] - 1$.

For an infinitesimal temperature drop eqn. (4.37) combined with eqns. (4.38) and (4.39) gives, with little error,

$$\frac{dT}{dT_d} = \left(\frac{c_x}{c_{xd}} \right)^2 = \left(\frac{T_d}{T} \right)^{2n} \left(\frac{\dot{m}}{\dot{m}_d} \right)^2. \quad (4.40)$$

Integrating eqn. (4.40),

$$T^{2n+1} = \left(\frac{\dot{m}}{\dot{m}_d} \right)^2 T_d^{2n+1} + K,$$

where K is an arbitrary constant.

To establish a value for K it is noted that if the turbine entry temperature is constant $T_d = T_1$ and $T = T_1$ also. Thus, $K = [1 + (\dot{m}/\dot{m}_d)^2] T_1^{2n+1}$ and

$$\left(\frac{T}{T_1} \right)^{2n+1} - 1 = \left(\frac{\dot{m}}{\dot{m}_d} \right)^2 \left[\left(\frac{T_d}{T_1} \right)^{2n+1} - 1 \right]. \quad (4.41)$$

Equation (4.41) can be rewritten in terms of pressure ratio since $T/T_1 = (p/p_1)^{\eta_p(\gamma-1)/\gamma}$. As $2n+1 = 2\gamma/[\eta_p(\gamma-1)] - 1$, then

$$\frac{\dot{m}}{\dot{m}_d} = \left\{ \frac{1 - (p/p_1)^{2-\eta_p(\gamma-1)/\gamma}}{1 - (p_d/p_1)^{2-\eta_p(\gamma-1)/\gamma}} \right\}^{1/2}. \quad (4.42a)$$

With $\eta_p = 0.9$ and $\gamma = 1.3$ the pressure ratio index is about 1.8; thus, the approximation is often used:

$$\frac{\dot{m}}{\dot{m}_d} = \left\{ \frac{1 - (p/p_1)^2}{1 - (p_d/p_1)^2} \right\}^{1/2}, \quad (4.42b)$$

which is the ellipse law of a multi-stage turbine.

PROBLEMS

1. Show, for an axial flow turbine stage, that the *relative* stagnation enthalpy across the rotor row does not change. Draw an enthalpy–entropy diagram for the stage labelling all salient points. Stage reaction for a turbine is defined as the ratio of the static enthalpy drop in the rotor to that in the stage. Derive expressions for the reaction in terms of the flow angles and draw velocity triangles for reactions of 0.0, 0.5 and 1.0.

2. (i) An axial flow turbine operating with an overall stagnation pressure of 8 to 1 has a polytropic efficiency of 0.85. Determine the total-to-total efficiency of the turbine.
(ii) If the exhaust Mach number of the turbine is 0.3, determine the total-to-static efficiency.
(iii) If, in addition, the exhaust velocity of the turbine is 160 m/s, determine the inlet total temperature.

Assume for the gas that $C_p = 1.175 \text{ kJ/(kg K)}$ and $R = 0.287 \text{ kJ/(kg K)}$.

3. The mean blade radii of the rotor of a mixed flow turbine are 0.3 m at inlet and 0.1 m at outlet. The rotor rotates at 20,000 rev/min and the turbine is required to produce 430 kW. The flow velocity at nozzle exit is 700 m/s and the flow direction is at 70° to the meridional plane. Determine the absolute and relative flow angles and the absolute exit velocity if the gas flow is 1 kg/s and the velocity of the through-flow is constant through the rotor.
4. In a Parson's reaction turbine the rotor blades are similar to the stator blades but with the angles measured in the opposite direction. The efflux angle relative to each row of blades is 70° from the axial direction, the exit velocity of steam from the stator blades is 160 m/s, the blade speed is 152.5 m/s, and the axial velocity is constant. Determine the specific work done by the steam per stage. A turbine of 80% internal efficiency consists of 10 such stages as just described and receives steam from the stop valve at 1.5 MPa and 300°C . Determine, with the aid of a Mollier chart, the condition of the steam at outlet from the last stage.
5. Values of pressure (kPa) measured at various stations of a zero reaction gas turbine stage, all at the mean blade height, are shown in the table that follows:

Stagnation pressure	Static pressure
Nozzle entry 414	Nozzle exit 207
Nozzle exit 400	Rotor exit 200

The mean blade speed is 291 m/s, inlet stagnation temperature 1100 K, and the flow angle at nozzle exit is 70° measured from the axial direction. Assuming the magnitude and direction of the velocities at entry and exit of the stage are the same, determine the total-to-total efficiency of the stage. Assume a perfect gas with $C_p = 1.148 \text{ kJ/(kg } ^\circ\text{C)}$ and $\gamma = 1.333$.

6. In a certain axial flow turbine stage the axial velocity c_x is constant. The absolute velocities entering and leaving the stage are in the axial direction. If the flow coefficient c_x/U is 0.6 and the gas leaves the stator blades at 68.2° from the axial direction, calculate
 - (i) the stage loading factor, $\Delta W/U^2$;
 - (ii) the flow angles relative to the rotor blades;
 - (iii) the degree of reaction;
 - (iv) the total-to-total and total-to-static efficiencies.

The Soderberg loss correlation, eqn. (3.50) should be used.

7. An axial flow gas turbine stage develops 3.36 MW at a mass flow rate of 27.2 kg/s. At the stage entry the stagnation pressure and temperature are 772 kPa and 727°C , respectively. The static

pressure at exit from the nozzle is 482 kPa and the corresponding absolute flow direction is 72° to the axial direction. Assuming the axial velocity is constant across the stage and the gas enters and leaves the stage without any absolute swirl velocity, determine

- (i) the nozzle exit velocity;
- (ii) the blade speed;
- (iii) the total-to-static efficiency;
- (iv) the stage reaction.

The Soderberg correlation for estimating blade row losses should be used. For the gas assume that $C_p = 1.148$ kJ/(kg K) and $R = 0.287$ kJ/(kg K).

8. Derive an approximate expression for the total-to-total efficiency of a turbine stage in terms of the enthalpy loss coefficients for the stator and rotor when the absolute velocities at inlet and outlet are *not* equal. A steam turbine stage of high hub–tip ratio is to receive steam at a stagnation pressure and temperature of 1.5 MPa and 325°C , respectively. It is designed for a blade speed of 200 m/s and the following *blade* geometry was selected:

	Nozzles	Rotor
Inlet angle, degree	0	48
Outlet angle, degree	70.0	56.25
Space–chord ratio, s/l	0.42	—
Blade length–axial chord ratio, H/b	2.0	2.1
Maximum. thickness–axial chord	0.2	0.2

The deviation angle of the flow from the rotor row is known to be 3° on the evidence of cascade tests at the design condition. In the absence of cascade data for the nozzle row, the designer estimated the deviation angle from the approximation $0.19 \theta s/l$ where θ is the blade camber in degrees. Assuming the incidence onto the nozzles is zero, the incidence onto the rotor 1.04° , and the axial velocity across the stage is constant, determine

- (i) the axial velocity;
 - (ii) the stage reaction and loading factor;
 - (iii) the approximate total-to-total stage efficiency on the basis of Soderberg's loss correlation, assuming Reynolds number effects can be ignored;
 - (iv) by means of a large steam chart (Mollier diagram) the stagnation temperature and pressure at stage exit.
9. (a) A single-stage axial flow turbine is to be designed for zero reaction without any absolute swirl at rotor exit. At the nozzle inlet the stagnation pressure and temperature of the gas are 424 kPa and 1100 K, respectively. The static pressure at the mean radius between the nozzle row and rotor entry is 217 kPa and the nozzle exit flow angle is 70° . Sketch an appropriate Mollier diagram (or a T – s diagram) for *this* stage allowing for the effects of losses and sketch the corresponding velocity diagram. Hence, using Soderberg's correlation to calculate blade row losses, determine for the mean radius

- (i) the nozzle exit velocity;
- (ii) the blade speed;
- (iii) the total-to-static efficiency.

(b) Verify for this turbine stage that the total-to-total efficiency is given by

$$\frac{1}{\eta_{tt}} = \frac{1}{\eta_{ts}} - \left(\frac{\phi}{2}\right)^2,$$

where $\phi = c_x/U$. Hence, determine the value of the total-to-total efficiency. Assume for the gas that $C_p = 1.15 \text{ kJ/(kg K)}$ and $\gamma = 1.333$.

10. (a) Prove that the centrifugal stress at the root of an untapered blade attached to the drum of an axial flow turbomachine is given by

$$\sigma_c = \pi \rho_m N^2 A_x / 1800,$$

where ρ_m = density of blade material, N = rotational speed of drum, in rpm and A_x = area of the flow annulus.

- (b) The preliminary design of an axial-flow gas turbine stage with stagnation conditions at stage entry of $p_{01} = 400 \text{ kPa}$, $T_{01} = 850 \text{ K}$, is to be based upon the following data *applicable to the mean radius*:

Flow angle at nozzle exit, $\alpha_2 = 63.8^\circ$;
 Reaction, $R = 0.5$;
 Flow coefficient, $c_x/U_m = 0.6$;
 Static pressure at stage exit, $p_3 = 200 \text{ kPa}$;
 Estimated total-to-static efficiency, $\eta_{ts} = 0.85$.

Assuming that the axial velocity is unchanged across the stage, determine

- (i) the specific work done by the gas;
 - (ii) the blade speed;
 - (iii) the static temperature at stage exit.
- (c) The blade material has a density of 7850 kg/m^3 and the maximum allowable stress in the rotor blade is 120 MPa . Taking into account only the centrifugal stress, assuming untapered blades and constant axial velocity at all radii, determine for a mean flow rate of 15 kg/s
- (i) the rotor speed (rev/min);
 - (ii) the mean diameter;
 - (iii) the hub–tip radius ratio.

For the gas assume that $C_p = 1050 \text{ J/(kg K)}$ and $R = 287 \text{ J/(kg K)}$.

11. The design of a single-stage axial-flow turbine is to be based on constant axial velocity with axial discharge from the rotor blades directly to the atmosphere. The following design values have been specified:

Mass flow rate	16.0 kg/s
Initial stagnation temperature, T_{01}	1100 K

Initial stagnation pressure, p_{01}	230 kN/m ²
Density of blading material, ρ_m	7850 kg/m ³
Maximum allowable centrifugal stress at blade root	1.7×10^8 N/m ²
Nozzle profile loss coefficient, $Y_P = (p_{01} - p_{02})/(p_{02} - p_2)$	0.06
Taper factor for blade stressing, K	0.75

In addition the following may be assumed:

Atmospheric pressure, p_3	102 kPa
Ratio of specific heats, γ	1.333
Specific heat at constant pressure, C_P	1150 J/(kgK)

In the design calculations values of the parameters at the mean radius are as follows:

Stage loading coefficient, $\psi = \Delta W/U^2$	1.2
Flow coefficient, $\phi = c_x/U$	0.35
Isentropic velocity ratio, U/c_0	0.61

where $c_0 = \sqrt{2(h_{01} - h_{3ss})}$. Determine

- (i) the velocity triangles at the mean radius;
 - (ii) the required annulus area (based on the density at the mean radius);
 - (iii) the maximum allowable rotational speed;
 - (iv) the blade tip speed and the hub–tip radius ratio.
12. Draw the velocity triangles for a repeating stage of an axial turbine that has a blade speed of 200 m/s, a constant axial velocity of 100 m/s, a stator exit angle of 65° , and no interstage swirl. Assuming that the working fluid is air, calculate the stage loading coefficient and the degree of reaction of the machine.
13. Determine the total-to-total efficiency of a low speed axial turbine stage that at the design condition has a stator exit flow angle of 70° , zero swirl at inlet and exit, constant axial velocity, and 50% reaction. Assume that the kinetic energy loss coefficient of both the stator blades and the rotor blades is 0.09.

Axial-Flow Compressors and Ducted Fans

A solemn, strange and mingled air, 't was sad by fits, by starts was wild.

W. Collins, *The Passions*

5.1 INTRODUCTION

The idea of using a form of *reversed turbine* as an axial compressor is as old as the reaction turbine itself. It is recorded by Stoney (1937) that Sir Charles Parsons obtained a patent for such an arrangement as early as 1884. However, simply reversing a turbine for use as a compressor gives efficiencies that are, according to Howell (1945a), less than 40% for machines of high pressure ratio. Parsons actually built a number of these machines (circa 1900), with blading based upon improved propeller sections. The machines were used for blast furnace work, operating with delivery pressures between 10 and 100 kPa. The efficiency attained by these early, low pressure compressors was about 55%; the reason for this low efficiency is now attributed to blade stall. A high pressure ratio compressor (550 kPa delivery pressure) was also built by Parsons but is reported by Stoney to have “run into difficulties.” The design, comprising two axial compressors in series, was abandoned after many trials, the flow having proved to be unstable (presumably due to *compressor surge*). As a result of low efficiency, axial compressors were generally abandoned in favour of multi-stage centrifugal compressors with their higher efficiency of 70–80%.

It was not until 1926 that any further development on axial compressors was undertaken, when A. A. Griffith outlined the basic principles of his aerofoil theory of compressor and turbine design. The subsequent history of the axial compressor is closely linked with that of the aircraft gas turbine and has been recorded by Cox (1946) and Constant (1945). The work of the team under Griffith at the Royal Aircraft Establishment, Farnborough, led to the conclusion (confirmed later by rig tests) that efficiencies of at least 90% could be achieved for “small” stages, i.e., low pressure ratio stages.

The early difficulties associated with the development of axial-flow compressors stemmed mainly from the fundamentally different nature of the flow process compared with that in axial-flow turbines. Whereas in the axial turbine the flow relative to each blade row is *accelerated*, in axial compressors it is *decelerated*. It is now widely known that although a fluid can be rapidly accelerated through a passage and sustain a small or moderate loss in total pressure the same is not true for a rapid deceleration. In the latter case large losses would arise as a result of severe stall caused by a large adverse pressure gradient. So as to limit the total pressure losses during flow diffusion it is necessary for the rate of deceleration (and turning) in the blade passages to be severely restricted. (Details of

these restrictions are outlined in Chapter 3 in connection with the correlations of Lieblein and Howell.) It is mainly because of these restrictions that axial compressors need to have many stages for a given pressure ratio compared with an axial turbine, which needs only a few. Thus, the reversed turbine experiment tried by Parsons was doomed to a low operating efficiency.

The performance of axial compressors depends on their usage category. Carchedi and Wood (1982) described the design and development of a single-shaft 15-stage axial-flow compressor that provided a 12 to 1 pressure ratio at a mass flow of 27.3 kg/s for a 6 MW industrial gas turbine. The design was based on subsonic flow and the compressor was fitted with variable stagger stator blades to control the position of the low-speed surge line. In the field of aircraft gas turbines, however, the engine designer is more concerned with *maximising* the work done per stage while retaining an acceptable level of overall efficiency. Increased stage loading almost inevitably leads to some aerodynamic constraint. This constraint is more severe at increased Mach number, when shock-induced boundary layer separation or increased losses can arise from poor diffusion of the flow. Wennerstrom (1990) outlined the history of highly loaded axial-flow compressors with special emphasis on the importance of reducing the number of stages and the ways that improved performance can be achieved. Since about 1970 a significant and special change occurred with respect to one design feature of the axial compressor and that was the introduction of low aspect ratio blading. It was not at all obvious why blading of large chord would produce any performance advantage, especially as the trend was to try to make engines more compact and lighter by using high aspect ratio blading. Wennerstrom (1989) reviewed the increased usage of low aspect ratio blading in aircraft axial-flow compressors and reported on the high loading capability, high efficiency, and good range obtained with this type of blading. One early application was an axial-flow compressor that achieved a pressure ratio of 12.1 in only five stages, with an isentropic efficiency of 81.9% and an 11% stall margin. The blade tip speed was 457 m/s and the flow rate per unit frontal area was 192.5 kg/s/m². It was reported that the mean aspect ratio ranged from a “high” of 1.2 in the first stage to less than 1.0 in the last three stages. A related later development pursued by the U.S. Air Force was an alternative inlet stage with a rotor mean aspect ratio of 1.32 that produced, at design, a pressure ratio of 1.912 with an isentropic efficiency of 85.4% and an 11% stall margin. A maximum efficiency of 90.9% was obtained at a pressure ratio of 1.804 and lower rotational speed.

The flow within an axial-flow compressor is exceedingly complex, which is one reason why research and development on compressors has proliferated over the years. In the following pages a very simplified and basic study is made of this compressor so that the student can grasp the essentials.

5.2 MEAN-LINE ANALYSIS OF THE COMPRESSOR STAGE

Most of the analysis in this chapter is simplified (as it was for axial turbines) by considering the variation in the flow along a mean radius through the machine. Significant spanwise variations are neglected and the parameters determined using this type of analysis are those representative of average conditions. This approach is appropriate for initial design and performance calculations of a compressor and it is more accurate if the blade height is small compared with the mean radius. In addition, as for axial turbines, the flow is assumed to be invariant in the circumferential direction, with negligible spanwise (radial) velocities. The three-dimensional flow effects that occur within axial turbomachines are considered within Chapter 6.

To illustrate the layout of an axial compressor, Figure 5.1(a) shows a sectional drawing of the three-shaft compressor system of the Rolls-Royce RB211 gas turbine engine. The very large blade on the left is part of the fan rotor, which is on one shaft; this is followed by two six-stage compressors of the “core” engine, each on its own shaft. A *compressor stage* is defined as a rotor blade row followed by a stator blade row. Figure 5.1(b) shows some of the blades of the first stage of the low-pressure compressor opened out into a plane array. The rotor blades (black) are fixed to the rotor drum and the stator blades are fixed to the outer casing. The blades upstream of the first rotor row are inlet guide vanes. These are not considered to be a part of the first stage and are treated separately. Their function is quite different from the other blade rows since, by directing

FIGURE 5.1

Axial-Flow Compressor and Blading Arrays: (a) Section of the Compression System of the RB211-535E4 Gas-Turbine Engine (courtesy of Rolls-Royce plc); (b) Development of the First Stage-Blade Rows and Inlet Guide Vanes

the flow away from the axial direction, they act to *accelerate* the flow rather than diffuse it. Functionally, inlet guide vanes are the same as turbine nozzles; they increase the kinetic energy of the flow at the expense of the pressure energy.

5.3 VELOCITY DIAGRAMS OF THE COMPRESSOR STAGE

The velocity diagrams for the stage are given in Figure 5.2 and the convention is adopted throughout this chapter of accepting all angles and swirl velocities in this figure as positive. As for axial turbine stages, a *normal* compressor stage is one where the absolute velocities and flow directions at stage outlet are the same as at stage inlet. The flow from a previous stage (or from the guide vanes) has a velocity c_1 and direction α_1 ; subtracting vectorially the blades speed U gives the inlet relative velocity w_1 at angle β_1 (the axial direction is the datum for all angles). Relative to the blades of the rotor, the flow is turned to the direction β_2 at outlet with a relative velocity w_2 . By vectorially adding the blade speed U onto w_2 gives the absolute velocity from the rotor, c_2 at angle α_2 . The stator blades deflect the flow towards the axis and the exit velocity is c_3 at angle α_3 . For the normal repeating stage in a multi-stage compressor, $c_3 = c_1$ and $\alpha_3 = \alpha_1$. In Figure 5.2, it will be noticed that both the relative velocity in the rotor and the absolute velocity in the stator decrease. As shown later in this chapter, this diffusion of kinetic energy in the rotor and stator rows, significantly influences the stage efficiency.

FIGURE 5.2

Velocity Diagrams for a Compressor Stage

5.4 THERMODYNAMICS OF THE COMPRESSOR STAGE

The specific work done by the rotor on the fluid, from the steady flow energy equation (assuming adiabatic flow) and momentum equation is

$$\Delta W = \dot{W}_p / \dot{m} = h_{02} - h_{01} = U(c_{\theta 2} - c_{\theta 1}). \quad (5.1)$$

In Chapter 1 it was shown that the Euler work equation can be written as $h_{0,\text{rel}} - U^2 = \text{constant}$. For axial machines where there is no radial shift of the streamlines across the rotor (i.e., $U_1 = U_2$), then $h_{0,\text{rel}} = h + \frac{1}{2}w^2$ is constant in the rotor. Thus,

$$h_1 + \frac{1}{2}w_1^2 = h_2 + \frac{1}{2}w_2^2. \quad (5.2)$$

Across the stator, h_0 is constant, and

$$h_2 + \frac{1}{2}c_2^2 = h_3 + \frac{1}{2}c_3^2. \quad (5.3)$$

The compression process for the complete stage is represented on a Mollier diagram in Figure 5.3, which is generalised to include the effects of irreversibility.

FIGURE 5.3

Mollier Diagram for an Axial Compressor Stage

5.5 STAGE LOSS RELATIONSHIPS AND EFFICIENCY

From eqns. (5.1) and (5.3) the actual work performed by the rotor on unit mass of fluid is $\Delta W = h_{03} - h_{01}$. The reversible or *minimum* work required to attain the same final stagnation pressure as the real process is

$$\Delta W_{\min} = h_{03ss} - h_{01} = (h_{03} - h_{01}) - (h_{03} - h_{03ss}).$$

Applying the equation for the second law of thermodynamics, $Tds = dh - dp/\rho$, along the curve of constant pressure, $p = p_{03}$, the approximation that $\Delta h = T\Delta s$ can be used such that

$$\Delta W_{\min} \cong \Delta W - T_{03}\Delta s_{\text{stage}},$$

where Δs_{stage} is the total entropy change through the stage such that $\Delta s_{\text{stage}} = \Delta s_{\text{rotor}} + \Delta s_{\text{stator}}$. The total-to-total efficiency of the compressor stage can therefore be written as

$$\eta_{tt} = \frac{\Delta W_{\min}}{\Delta W} \cong 1 - \frac{T_{03}\Delta s_{\text{stage}}}{h_{03} - h_{01}}. \quad (5.4)$$

Note also that the total-to-static efficiency, as defined in Chapter 1, is given by

$$\eta_{ts} = \frac{h_{3ss} - h_{01}}{h_{03} - h_{01}} \cong \frac{h_{03} - h_{01} - (h_{03} - h_{3ss})}{h_{03} - h_{01}} \cong 1 - \frac{0.5c_3^2 + T_3\Delta s_{\text{stage}}}{h_{03} - h_{01}}. \quad (5.5)$$

Therefore, to determine the efficiency of the stage, we need to determine the entropy changes through the rotor and stator. This can be done by using the loss coefficients, $Y_{p,\text{rotor}}$ and $Y_{p,\text{stator}}$. These loss coefficients could be those determined by two-dimensional cascade tests or computational analysis (see Chapter 3). The loss coefficients are defined as

$$Y_{p,\text{rotor}} = \frac{p_{01,\text{rel}} - p_{02,\text{rel}}}{p_{01,\text{rel}} - p_1}$$

and

$$Y_{p,\text{stator}} = \frac{p_{02} - p_{03}}{p_{02} - p_2}. \quad (5.6)$$

Consider the process of a perfect gas passing through the rotor at constant relative stagnation enthalpy, $h_{01,\text{rel}}$. The second law of thermodynamics, $Tds = dh - dp/\rho$, can be written for this process as

$$T_{01,\text{rel}}\Delta s_{\text{rotor}} \cong \frac{\Delta p_{0,\text{rotor}}}{\rho_{01,\text{rel}}},$$

where

$$\Delta p_{0,\text{rotor}} = p_{01,\text{rel}} - p_{02,\text{rel}}. \quad (5.7)$$

Using the equation of state, $p = \rho RT$, this can be written as

$$\Delta s_{\text{rotor}} \cong \frac{R\Delta p_{0,\text{rotor}}}{p_{01,\text{rel}}} = RY_{p,\text{rotor}}(1 - p_1/p_{01,\text{rel}}). \quad (5.8)$$

Note that the negative sign in the Tds equation disappears since the relative stagnation pressure is decreasing through the rotor, giving an increase in entropy. Also note that a key advantage of using entropy here is that it is independent of the frame of reference in which it is evaluated. The entropy

change through the stator is found similarly to that for the rotor, and the total entropy change through the stage is simply the sum of the two. In terms of the loss coefficients,

$$\Delta s_{\text{stage}} = \Delta s_{\text{rotor}} + \Delta s_{\text{stator}} \cong R[Y_{p,\text{rotor}}(1 - p_1/p_{01,\text{rel}}) + Y_{p,\text{stator}}(1 - p_2/p_{02})]. \quad (5.9)$$

Hence, the total-to-total efficiency can be written as

$$\eta_{tt} \cong 1 - \frac{(\gamma - 1)}{\gamma} \frac{[Y_{p,\text{rotor}}(1 - p_1/p_{01,\text{rel}}) + Y_{p,\text{stator}}(1 - p_2/p_{02})]}{1 - T_{01}/T_{03}}. \quad (5.10)$$

For a low speed machine, where the flow is incompressible as well as the density being constant, it can be assumed that temperature changes throughout the stage are relatively small. Applying the second law equation, $Tds = dh - dp/\rho$, for the flow through the rotor and the stator then gives

$$T\Delta s_{\text{rotor}} \cong \frac{\Delta p_{0,\text{rotor}}}{\rho} = \frac{1}{2} w_1^2 Y_{p,\text{rotor}}$$

and

$$T\Delta s_{\text{stator}} \cong \frac{\Delta p_{0,\text{stator}}}{\rho} = \frac{1}{2} c_2^2 Y_{p,\text{stator}}. \quad (5.11)$$

Thus, by combining eqns. (5.4) and (5.11), the efficiency can be expressed for a low speed machine as

$$\eta_{tt} \cong 1 - \frac{T\Delta s_{\text{stage}}}{h_{03} - h_{01}} = 1 - \frac{\Delta p_{0,\text{rotor}} + \Delta p_{0,\text{stator}}}{\rho(h_{03} - h_{01})} \quad (5.12a)$$

or as

$$\eta_{tt} \cong 1 - \frac{0.5(w_1^2 Y_{p,\text{rotor}} + c_2^2 Y_{p,\text{stator}})}{h_{03} - h_{01}}. \quad (5.12b)$$

5.6 MEAN-LINE CALCULATION THROUGH A COMPRESSOR ROTOR

Calculation of the flow through a row of rotor blades is similar to that through a stationary cascade, as described in Chapter 3. The minor complication is the use of relative rather than absolute properties.

Compressible Case

Consider the transonic compressor rotor shown in Figure 5.4. The velocity triangle at inlet has been scaled so that it is a Mach number triangle, which is often a useful transformation for high speed stages.

If the conditions at inlet to the rotor are known, the non-dimensional mass flow rate at inlet can be determined from compressible flow tables:

$$\frac{\dot{m} \sqrt{C_p T_{01,\text{rel}}}}{A_{1n} p_{01,\text{rel}}} = \frac{\dot{m} \sqrt{C_p T_{01,\text{rel}}}}{Hs \cos \beta_1 p_{01,\text{rel}}} = Q(M_{1,\text{rel}}),$$

where A_{1n} is the area normal to the flow at inlet, and the projected frontal area of the rotor (or annulus area) is Hs and taken to be constant through the rotor. To find the conditions at exit, the

**FIGURE 5.4**

Mean-Line Flow through a High Speed Compressor Rotor

non-dimensional mass flow rate at exit can be written in terms of the preceding, using the fact that through a rotor blade with constant mean radius, $T_{01,rel} = T_{02,rel}$:

$$Q(M_{2,rel}) = \frac{\dot{m} \sqrt{C_p T_{02,rel}}}{H s \cos \beta_2 p_{02,rel}} = Q(M_{1,rel}) \times \frac{p_{01,rel}}{p_{02,rel}} \times \frac{\cos \beta_1}{\cos \beta_2}. \quad (5.13)$$

The ratio of relative total pressures can be determined from the rotor loss coefficient. Using the definition given in eqn. (5.6),

$$\frac{p_{02,rel}}{p_{01,rel}} = 1 - Y_{p,rotor} (1 - p_1/p_{01,rel}). \quad (5.14)$$

Once the exit relative Mach number and flow angle from the rotor blade are known, the other properties at exit from the rotor can be determined (via compressible flow relations and the velocity triangle) in order to fully specify the conditions at inlet to the stator. This is demonstrated later in Example 5.1.

Incompressible Case

In the low speed, incompressible, case the equivalent calculations are more straightforward. The continuity equation reduces to

$$\rho H s \cos \beta_1 w_1 = \rho H s \cos \beta_2 w_2 \Rightarrow \frac{w_2}{w_1} = \frac{\cos \beta_1}{\cos \beta_2}. \quad (5.15)$$

The loss in relative total pressure through the rotor can be related to the loss coefficient, since $P_{01,rel} = P_{02,rel} - \frac{1}{2} \rho w_1^2 Y_{p,rotor}$. The static pressure at rotor exit can therefore be found as follows:

$$p_2 = p_{02,rel} - \frac{1}{2} \rho w_2^2 = p_{01,rel} - \frac{1}{2} \rho (w_1^2 Y_{p,rotor} + w_2^2). \quad (5.16)$$

Once the exit static pressure is known all other quantities at rotor exit can be found since the density is fixed and the velocities are known.

Example 5.1

A single-stage transonic compressor operates with axial flow at inlet. The inlet absolute stagnation temperature is 288 K and the inlet absolute stagnation pressure is 101 kPa. The relative flow angle at inlet to the rotor is 45° and the inlet relative Mach number is 0.9.

- (i) Calculate the rotor blade speed and the inlet relative stagnation pressure.
- (ii) The mean radius and the mass flow rate per unit annulus area are constant through the rotor. If the rotor loss coefficient is 0.068 and the rotor exit relative Mach number is 0.5, find the rotor exit relative flow angle and determine the static pressure ratio across the rotor.
- (iii) Show that the absolute stagnation temperature and pressure at entry to the stator are 322 K and 145 kPa, respectively. Determine the total-to-total isentropic efficiency of the compressor stage if the stagnation pressure loss coefficient for the stator is 0.04.

Solution

- (i) $T_{01} = 288$ K, $p_{01} = 101$ kPa. Given that the flow is axial at inlet, the absolute inlet Mach number can be calculated (using the Mach number triangles shown in Figure 5.4):

$$M_1 = M_{1,rel} \cos 45^\circ = 0.9 / \sqrt{2} = 0.6364.$$

The inlet static temperature can be calculated from the inlet Mach number and inlet stagnation temperature as follows:

$$T_1 = T_{01} \left(1 + (\gamma - 1) M_1^2 / 2 \right)^{-1} = 266.4 \text{ K}.$$

The blade speed can then be determined from the inlet Mach number triangle and the fact that the relative inflow angle is 45° :

$$U = M_1 \sqrt{\gamma R T_1} = 0.634 \times \sqrt{1.4 \times 287.15 \times 266.4} = \underline{208.3 \text{ m/s}}.$$

The blade relative stagnation pressure can be found from compressible flow tables:

$$p_{01,rel} = \frac{p_{01} \times p_1 / p_{01}}{p_1 / p_{01,rel}} = \frac{101 \times 0.7614}{0.5913} = \underline{130 \text{ kPa}}.$$

Note that $p_1 = 101 \times 0.7614 = 76.9$ kPa.

(ii) To relate the conditions across the rotor, first calculate the ratio of relative stagnation pressures:

$$Y_P = \frac{1 - p_{02,rel}/p_{01,rel}}{1 - p_1/p_{01,rel}}, \text{ which implies that } \frac{p_{02,rel}}{p_{01,rel}} = 1 - Y_P(1 - p_1/p_{01,rel}).$$

Therefore,

$$\frac{p_{02,rel}}{p_{01,rel}} = 1 - 0.068 \times (1 - 0.5913) = 0.9722.$$

Applying continuity across the rotor,

$$\frac{\dot{m} \sqrt{c_p T_{01,rel}}}{A_x \cos \beta_1 p_{01,rel}} = Q(M_{1,rel}) = \frac{\dot{m} \sqrt{c_p T_{02,rel}}}{A_x \cos \beta_2 p_{02,rel}} \times \frac{\cos \beta_2}{\cos \beta_1} \times \frac{p_{02,rel}}{p_{01,rel}}.$$

Therefore,

$$\cos \beta_2 = \frac{Q(M_{1,rel})}{Q(M_{2,rel})} \times \cos \beta_1 \times \frac{p_{01,rel}}{p_{02,rel}}.$$

This is true since $T_{02,rel} = T_{01,rel}$ (constant radius) and \dot{m}/A_x is constant. Putting in the values from the question and using the compressible flow tables,

$$\cos \beta_2 = \frac{Q(0.9)}{Q(0.5)} \times \cos 45^\circ \times \frac{1}{0.9722} = \frac{1.2698}{0.9561} \times \frac{1}{\sqrt{2}} \times \frac{1}{0.9722} = 0.9659,$$

which implies that

$$\beta_2 = 15^\circ (\text{angles are } +ve)$$

The static pressure ratio is then determined from the various ratios just derived:

$$\frac{p_2}{p_1} = \frac{p_2/p_{02,rel} \times p_{02,rel}/p_{01,rel}}{p_1/p_{01,rel}} = \frac{0.8430 \times 0.9722}{0.5913} = 1.386.$$

Note that $p_2 = 0.8430 \times 0.9722 \times 130 = 106.6$ kPa.

(iii) To calculate the conditions at stator inlet, apply the exit Mach number triangle from the rotor (as shown in Figure 5.4) to convert the properties from the relative to absolute frame of reference. Using the compressible flow tables, the static temperature and relative velocity at rotor exit can be found:

$$T_2 = \frac{T_1 \times T_2/T_{02,rel}}{T_1/T_{01,rel}} = \frac{266.4 \times 0.9524}{0.8606} = 294.8 \text{ K (since } T_{02,rel} = T_{01,rel})$$

$$W_2 = M_{2,rel} \sqrt{\gamma R T_2} = 0.5 \times \sqrt{1.4 \times 287.15 \times 294.8} = 172.1 \text{ m/s}.$$

The velocity triangle can be used to find the absolute flow Mach number, which is needed to determine the absolute stagnation quantities:

$$M_2 = \frac{c_2}{\sqrt{\gamma R T_2}} = \frac{\sqrt{(W_2 \cos 15^\circ)^2 + (U - W_2 \sin 15^\circ)^2}}{\sqrt{\gamma R T_2}} = 0.6778.$$

It then follows that

$$T_{02} = T_2[1 + (\gamma - 1) M_2^2/2] = \underline{321.9 \text{ K}}$$

$$p_{02} = p_2 \left(1 + (\gamma - 1) M_2^2/2\right)^{\gamma/(\gamma-1)} = \underline{145 \text{ kPa.}}$$

The overall stage efficiency can now be calculated, using eqns. (5.4) and (5.8):

$$\eta_{TT} = \frac{T_{02s} - T_{01}}{T_{02} - T_{01}} = 1 - \frac{T_{02} - T_{02s}}{T_{02} - T_{01}} = 1 - \frac{T_{02}(\Delta s_{\text{rotor}} + \Delta s_{\text{stator}})/c_p}{T_{02} - T_{01}},$$

which implies that

$$\Delta s_{\text{rotor}} = RY_P \left(1 - \frac{p_1}{p_{01,\text{rel}}}\right) = 287.15 \times 0.068 \times (1 - 76.9/130) = 7.98 \text{ J/kgK}$$

and

$$\Delta s_{\text{stator}} = RY_P \left(1 - \frac{p_2}{p_{02}}\right) = 287.15 \times 0.04 \times (1 - 106.6/145) = 3.04 \text{ J/kgK.}$$

Thus,

$$\eta_{TT} = 1 - \frac{321.9 \times (7.98 + 3.04)/1005}{321.9 - 288} = \underline{0.896}.$$

This is a realistic efficiency value for a single-stage transonic compressor.

5.7 PRELIMINARY COMPRESSOR STAGE DESIGN

By fixing the stage loading ψ , the flow coefficient ϕ , and the reaction R , the velocity triangles at the design condition are specified. However, as well as fixing the velocity triangles such that the compressor will achieve the required pressure rise with high efficiency, it is critically important for a compressor that it operates with an adequate stability margin. As will be explained later in this chapter, if too much pressure rise is demanded of a compressor it can become unstable and enter an unacceptable operating regime (stall or surge). The choice of the velocity triangle parameters is therefore a compromise between the best performance at the design condition and sufficient operating range.

Many axial compressors are multi-stage devices and, for simplicity, *repeating stages* are initially assumed in which the velocity triangles for all stages are similar, the mean radius is constant, and the axial velocity through the machine is constant. In such machines the flow coefficient, stage loading and reaction are the same in every stage.

Note that this section only briefly covers the main preliminary design considerations and the associated mean-line analysis. If further details are needed, a complete description of the compressor design process can be found in Gallimore (1999).

Stage Loading

The blades of a compressor behave like diffusers, each row of rotors and stators slowing down the local relative velocity (see Chapter 3). The amount of diffusion possible is limited, because if too much diffusion is demanded, the flow will separate from the blades leading to compressor stall or

surge. DeHaller (1953) proposed that the relative velocity at exit from a blade row should be at least 75% of the inlet relative velocity for satisfactory performance. This is equivalent to limiting the pressure rise across each blade row and the maximum stage loading possible.

The stage loading ψ for a *normal*, or repeating, stage can be written as

$$\psi = \frac{h_{03} - h_{01}}{U^2} = \frac{\Delta c_\theta}{U} = \frac{c_{\theta 2} - c_{\theta 1}}{U} = \phi(\tan \alpha_2 - \tan \alpha_1). \quad (5.17a)$$

Referring to the velocity triangles in Figure 5.2, it is clear that $c_{\theta 1} = U - w_{y1}$ and $c_{\theta 2} = U - w_{y2}$. Thus, this equation can be rewritten as

$$\psi = \phi(\tan \beta_1 - \tan \beta_2), \quad (5.17b)$$

or,

$$\psi = 1 - \phi(\tan \alpha_1 + \tan \beta_2), \quad (5.17c)$$

where $\phi = c_x/U$ is the flow coefficient.

The choice of stage loading at the compressor design point is critical. A value that is too low will lead to an excessive number of compressor stages to achieve a required pressure ratio. A value that is too high will limit the operating range of the compressor and increase the number of aerofoils needed to remove the risk of flow separation. As shown in Chapter 3, Lieblein's diffusion factor, DF, is a useful parameter for determining the blade pitch–chord ratio needed for acceptable performance. Based on eqn. (3.32), this can be written for a compressor rotor as

$$DF = \left(1 - \frac{w_2}{w_1}\right) + \frac{\Delta c_\theta}{2w_1} \frac{s}{l}. \quad (5.18)$$

A larger stage loading requires more flow turning Δc_θ and, therefore, to maintain an acceptable level of diffusion, the pitch–chord ratio of the blades must be reduced. This leads to a higher number of aerofoils, which tends to increase profile losses due to the higher wetted area and also leads to problems at high Mach numbers since the increased number of aerofoils will increase the likelihood of choking. For these reasons pitch-to-chord ratios are typically in the range 0.8 to 1.2 and the stage loading is limited to values around 0.4. However, more advanced compressor designs for aero-engines, where the need to reduce the number of stages is most pressing, may have higher stage loadings.

Flow Coefficient

From eqn (5.17b), $\psi = \phi(\tan \beta_1 - \tan \beta_2)$, which shows that for a fixed stage loading, as the flow coefficient increases, the flow turning required reduces. Hence, the diffusion through the blades is found to reduce as flow coefficient increases. Equally, for a fixed level of diffusion, the stage loading can increase as the flow coefficient rises. This suggests that a high flow coefficient is beneficial. In addition, higher values of flow coefficient correspond to higher inlet mass flow per unit area, which is a significant advantage as it implies a smaller diameter machine for a given mass flow.

However, in axial compressors, stage performance is often limited by Mach number effects and, for a fixed level of blade speed, high values of flow coefficient will lead to higher relative Mach number and potentially greater losses from choking and shock waves. Another disadvantage of a higher flow

coefficient design concerns the tolerance of the compressor to non-uniform inflow. Compressors need to remain stable in the event of a disturbance in the inlet flow, and lower flow coefficient designs are found to absorb fluctuations more readily than high flow coefficient designs. The reasons for this are detailed in Smith (1958).

As a result of these considerations, typical values of ϕ used in designs are between 0.4 and 0.8 and often, for initial designs, 0.5 is chosen.

Reaction

The general definition of R for a compressor is the ratio of the rotor static enthalpy rise to the stage static enthalpy rise:

$$R = (h_2 - h_1)/(h_3 - h_1). \quad (5.19)$$

From eqn. (5.2), $h_2 - h_1 = \frac{1}{2}(w_1^2 - w_2^2)$. For normal stages ($c_1 = c_3$), $h_3 - h_1 = h_{03} - h_{01} = U(c_{\theta 2} - c_{\theta 1})$. Substituting into eqn. (5.19),

$$R = \frac{w_1^2 - w_2^2}{2U(c_{\theta 2} - c_{\theta 1})} = \frac{(w_{\theta 1} + w_{\theta 2})(w_{\theta 1} - w_{\theta 2})}{2U(c_{\theta 2} - c_{\theta 1})}, \quad (5.20)$$

where it is assumed that c_x is constant across the stage. From Figure 5.2, $c_{\theta 2} = U - w_{\theta 2}$ and $c_{\theta 1} = U - w_{\theta 1}$ so that $c_{\theta 2} - c_{\theta 1} = w_{\theta 1} - w_{\theta 2}$. Thus,

$$R = (w_{\theta 1} + w_{\theta 2})/(2U) = \frac{1}{2}\phi(\tan \beta_1 + \tan \beta_2). \quad (5.21)$$

An alternative useful expression for the reaction can be found in terms of the fluid outlet angles from each blade row in a stage. With $w_{\theta 1} = U - c_{\theta 1}$, eqn. (5.21) gives

$$R = \frac{1}{2} + (\tan \beta_2 - \tan \alpha_1)\phi/2. \quad (5.22)$$

Eliminating β_2 between eqs. (5.22) and (5.17c) gives an equation in ψ , ϕ , and R and the inter-stage swirl angle, α_1

$$\psi = 2(1 - R - \phi \tan \alpha_1). \quad (5.23)$$

Equation (5.23) is identical to eqn. (4.14) derived for turbines, except for the sign convention. This equation shows that a higher reaction tends to reduce the stage loading, which is good for a compressor. However, stages having 50% reaction are widely used as the adverse (retarding) pressure gradient through the rotor rows and stator rows are equally shared. A 50% reaction also means that the rotor and stator blades will have similar shapes. Parametric design studies, as presented in Cumpsty (1989), suggest that the reaction is not such a critical parameter in determining compressor efficiency. In fact, in many cases, the reaction is not a free design variable since it is determined by other factors. For example, in a design where the stage loading and flow coefficients have already been chosen, if the inlet swirl angle α_1 is fixed, either by having an axial inlet flow or inlet guide vanes, then the reaction must also be fixed (as indicated by eqn. 5.23).

**FIGURE 5.5**

Asymmetry of Velocity Diagrams for Reactions Greater or Less than 50%

In advanced compressor designs, particularly in jet engine compressors, high reaction is common and values between 0.5 and 0.8 are typical.

If $R = 0.5$, then $\alpha_1 = \beta_2$ from eqn. (5.22), and the velocity diagram is symmetrical. The stage enthalpy rise is equally distributed between the rotor and stator rows.

If $R > 0.5$ then $\beta_2 > \alpha_1$ and the velocity diagram is skewed to the *right* as shown in Figure 5.5(a). The static enthalpy rise in the rotor exceeds that in the stator (this is also true for the static pressure rise).

If $R < 0.5$ then $\beta_2 < \alpha_1$ and the velocity diagram is skewed to the *left* as indicated in Figure 5.5(b). Clearly, the stator enthalpy (and pressure) rise exceeds that in the rotor.

Inter-Stage Swirl

From eqn. 5.23 it can be seen that introducing positive swirl between the stages helps reduce stage loading. Positive swirl also reduces the relative inlet Mach number at inlet to the rotor. Therefore, advanced multi-stage compressors, particularly those within gas turbines, will often have an inter-stage swirl angle of around 20 to 30 degrees.

Blade Aspect Ratio

Once ψ , ϕ , and R are fixed at the design condition, the number of stages for a multi-stage compressor can be determined (see Example 5.2). Given a mass flow and blade speed, the mean radius of the compressor and the blade heights can also be calculated, using the calculations shown in Chapter 4. The overall compressor length and the number of blades can then be estimated by choosing suitable values of aspect ratio, H/l , for each blade row.

The choice of aspect ratio is important as this influences the blade losses and the stage stability margin. Lower aspect ratios will tend to have greater losses due to increased wetted area and the

build up of boundary layers. However, as shown in Koch (1997), lower aspect ratios tend to give higher surge margin. This is why modern multi-stage compressors have lower aspect ratio values than might be expected, and 1–2 is typical.

The choice of aspect ratio, combined with the blade height, fixes the blade chord, l . The pitch-to-chord ratio, s/l , is determined by eqn (5.18) combined with a choice of an acceptable level of diffusion factor, DF. With the blade chord known this then sets the number of blades in each row.

The overall compressor length depends on the axial gaps between blade rows. These will be set to limit the vibration and noise generated by rotor–stator interaction and spaces between the rows of about half an axial chord are typical.

5.8 SIMPLIFIED OFF-DESIGN PERFORMANCE

Horlock (1958) considered how the stage loading ψ behaves with varying flow coefficient ϕ and how this off-design performance is influenced by the choice of design conditions. Cascade data appears to suggest that the fluid outlet angles β_2 (for the rotor) and $\alpha_1 (= \alpha_3)$ for the stator do not change appreciably for a range of incidence up to the stall point. The simplification was made that, for a given compressor stage,

$$\tan \alpha_1 + \tan \beta_2 = t = \text{constant.} \quad (5.24)$$

Inserting this expression into eqn. (5.17c) gives

$$\psi = 1 - \phi t. \quad (5.25a)$$

An inspection of eqns. (5.24) and (5.25a) suggests that, provided t is positive, the stage stagnation enthalpy rise, ψ , increases as the flow coefficient, ϕ , is reduced, when running at constant rotational speed. This is shown in Figure 5.6, where ψ is plotted against ϕ for several values of t .

Writing $\psi = \psi_d$ and $\phi = \phi_d$ for conditions at the design point, then

$$\psi_d = 1 - \phi_d t. \quad (5.25b)$$

The values of ψ_d and ϕ_d chosen for a particular stage design determines the value of t . It is instructive to learn how the off-design test results obtained from a compressor stage compare with the simplified performance model. The test results were obtained by Howell (1945) in the early days of axial-flow compressor design but they are still valid for our purpose. Figure 5.7 shows the variation of the stage loading coefficient ψ plotted against the flow coefficient ϕ . The design point for this stage is actually at about $\phi = 0.80$, which corresponds to the maximum efficiency condition. At this flow coefficient the relative flow angles are $\beta_1 = 45.8^\circ$ and $\beta_2 = 12.2^\circ$. From these data we can derive a value for $t = \tan \alpha_1 + \tan \beta_2$. Now,

$$\tan \alpha_1 = 1/\phi - \tan \beta_1 = 1/0.8 - \tan 45.8^\circ = 0.2217.$$

Hence,

$$t = \tan \alpha_1 + \tan \beta_1 = 0.2217 + 0.2166 = 0.4383.$$

**FIGURE 5.6**

Simplified Off-Design Performance of a Compressor Stage (adapted from Horlock, 1958)

**FIGURE 5.7**

Compressor Stage Performance Comparison of simplified Analysis with Measured Performance

Substituting for t in eqn. (5.25b) the theoretical relationship is found:

$$\psi = 1 - 0.438\phi,$$

which is plotted in Figure 5.7. The comparison of the measured results with the theoretical result clearly demonstrates that there is a fault in the assertion that the flow outlet angle from a blade row does not change. Away from the design point flow the gradual increase in the stage deviation angle has an increasing effect on the performance.

In Figure 3.25 some early test results obtained by Ainley (1948) clearly show the variation of gas outlet angles with change in incidence for two types of blade row (“impulse” and “reaction” blading). Although these changes may appear small they will be sufficient to cause the deviation from the straight line of eqn. (5.25a).

5.9 MULTI-STAGE COMPRESSOR PERFORMANCE

For preliminary design and analysis purposes, a multi-stage compressor is thought of as a series of single-stage compressors, each performing as it would in isolation. However, to understand the performance of a real machine, the behaviour of the overall system must be considered in more detail. This is particularly important to understand the sources of loss in a compressor and the off-design operation, as discussed later in this section.

Overall Pressure Ratio and Efficiency

It is possible to apply some of the earlier analysis to the determination of the overall pressure ratio of a multi-stage compressor. A possible procedure requires the calculation of pressure and temperature changes for a single stage, the stage exit conditions enabling the density at entry to the following stage to be found. This calculation can be repeated for each stage in turn until the required final conditions are satisfied. However, for compressors having *identical stages* it is more convenient to apply a simple compressible flow analysis for all the stages. An illustrative example follows.

Example 5.2

A multi-stage axial compressor is required for compressing air at 293 K, through a pressure ratio of 5 to 1. Each stage is to be a 50% reaction and the mean blade speed of 275 m/s, flow coefficient 0.5, and stage loading factor 0.3 are taken, for simplicity, as constant for all stages. Determine the flow angles and the number of stages required if the polytropic efficiency is 88.8%. Take $C_p = 1.005 \text{ kJ/(kg}^\circ\text{C)}$ and $\gamma = 1.4$ for air.

Solution

From eqn. (5.17b) the stage load factor can be written as

$$\psi = \phi(\tan \beta_1 - \tan \beta_2).$$

From eqn. (5.21) the reaction is

$$R = \frac{\phi}{2}(\tan \beta_1 + \tan \beta_2).$$

Solving for $\tan \beta_1$ and $\tan \beta_2$ gives

$$\tan \beta_1 = (R + \psi/2)/\phi$$

and

$$\tan \beta_2 = (R - \psi/2)/\phi.$$

Calculating β_1 and β_2 and observing for $R = 0.5$ that the velocity diagram is symmetrical,

$$\beta_1 = \alpha_2 = 52.45^\circ$$

and

$$\beta_2 = \alpha_1 = 35^\circ.$$

Writing the stage load factor as $\psi = C_p \Delta T_0 / U^2$, the stage stagnation temperature rise is

$$\Delta T_0 = \psi U^2 / C_p = 0.3 \times 275^2 / 1005 = 22.5^\circ\text{C}.$$

It is reasonable here to take the stage efficiency as equal to the polytropic efficiency since the stage temperature rise of an axial compressor is small. Denoting compressor inlet and outlet conditions by subscripts I and II, respectively, from eqn. (1.50),

$$\frac{T_{0II}}{T_{0I}} = 1 + \frac{n \Delta T_0}{T_{0I}} = \left(\frac{p_{0II}}{p_{0I}} \right)^{(\gamma-1)/\eta_p \gamma},$$

where n is the required number of stages. Thus,

$$n = \frac{T_{0I}}{\Delta T_0} \left[\left(\frac{p_{0II}}{p_{0I}} \right)^{(\gamma-1)/\eta_p \gamma} - 1 \right] = \frac{293}{22.5} \left[5^{1/3.11} - 1 \right] = 8.86.$$

A suitable number of stages is therefore 9.

The overall efficiency is found from eqn. (1.53):

$$\eta_{tt} = \left[\left(\frac{p_{0II}}{p_{0I}} \right)^{(\gamma-1)/\gamma} - 1 \right] / \left[\left(\frac{p_{0II}}{p_{0I}} \right)^{(\gamma-1)/\eta_p \gamma} - 1 \right] = \left[5^{1/3.5} - 1 \right] / \left[5^{1/3.11} - 1 \right] = 86.3\%.$$

Note that the total-to-total efficiency is significantly lower than the polytropic (or small stage) efficiency. This difference is to be expected, as shown in Chapter 1. It is more usual in compressor design and analysis to quote polytropic efficiencies, as these are independent of the pressure ratio of the multi-stage machine and therefore a fairer way to compare the losses.

Three-Dimensional Flow Effects

Although the subject matter of this chapter is concerned primarily with the one-dimensional variation in flow properties, the flow through a compressor is subject to many three-dimensional effects that have a significant impact on the compressor performance. In particular, annulus boundary layers build up on the compressor hub and casing. As well as leading to radial non-uniformity within the flow in each stage, these end wall flows cause blockage that reduces the mass flow that can be passed by the machine. In addition, these boundary layers interact with the flow within the blade passages, including the boundary layers on the blade surfaces, leading to significant secondary flows throughout the compressor and reduced efficiency.

Over the tips of rotor blades, a clearance gap is required. The flow through this clearance gap interacts with the end wall flow and the flow in the passage. This adds to the blockage, reducing the overall

flow capacity of the compressor stage and also, more seriously, reduces the stable operating range, see Freeman (1985). The aim is always to minimise the clearance gap to improve the stability margin and reduce the losses caused by leakage, but the minimum clearance is usually determined by manufacturing and mechanical considerations.

Leakage flows are found not only in the rotor tip gaps. Stator blades are often cantilevered from the compressor casing to minimise weight. This leads to a clearance gap at the stator hub. The leakage flow that arises can help relieve high diffusion at the stator hub, but it also adds to blockage and loss. In addition, leakage flows from the gaps and seals are present in the real geometry of a compressor.

These secondary flows will typically contribute up to 50% of the losses within a compressor (the other 50% coming from the blade profile loss that could be measured in a cascade). They lead to reduced flow capacity due to the additional blockage, reduced work input, and more limited operating range. They therefore need to be accounted for in the preliminary design by using average loss coefficients for the whole flow field and by factoring the velocity triangle parameters appropriately such that they represent the average flow conditions.

Annulus Wall Boundary Layers

In multi-stage axial compressors the annulus wall boundary layers rapidly thicken through the first few stages and the axial velocity profile becomes increasingly non-uniform. This effect is illustrated in Figure 5.8, from the experimental results of Howell (1945), which shows axial velocity traverses through a four-stage compressor. Over the central region of the blade, the axial velocity is higher than the mean value based on the through-flow. The mean blade section (and most of the span) will, therefore, do less work than is estimated from the velocity triangles based on the mean axial velocity. In theory it would be expected that the tip and root sections would provide a compensatory effect because of the low axial velocity in these regions. Due to stalling of these sections (and tip leakage) no such work increase actually occurs, and the net result is that the work done by the whole blade is below the design figure. Howell (1945) suggested that the stagnation enthalpy rise across a stage could be expressed as

$$h_{03} - h_{01} = \lambda U(c_{\theta 2} - c_{\theta 1}), \quad (5.26)$$

where λ is a *work done factor*. For multi-stage compressors Howell recommended for λ a mean value of 0.86. Other workers have suggested that λ should be high at entry (0.96) where the annulus wall boundary layers are thin, reducing progressively in the later stages of the compressor (0.85). Howell and Bonham (1950) have given mean work done factors for compressors with varying numbers of stages, as in Figure 5.9. For a four-stage compressor the value of λ would be 0.9, which would be applied to all four stages.

Smith (1970) commented upon the rather pronounced deterioration of compressor performance implied by the example given in Figure 5.8 and suggested that things are not as bad as suggested. Figure 5.10(a) shows the axial velocity distributions through a 12-stage axial compressor. This does illustrate that rapid changes in velocity distribution still occur in the first few stages, but that the profile settles down to a fairly constant shape thereafter. This phenomenon has been referred to as *ultimate steady flow*, which Horlock (2000) described as “a stage deeply embedded in the compressor where an axial equilibrium state is reached.”

**FIGURE 5.8**

Axial Velocity Profiles in a Compressor (Howell, 1945, courtesy of the Institution of Mechanical Engineers)

**FIGURE 5.9**

Mean Work Done Factor In Compressors (Howell and Bonham, 1950, courtesy of the Institution of Mechanical Engineers)

Smith also provided curves of the spanwise variation in total temperature, Figure 5.10(b), which shows the way losses increase from midpassage towards the annulus walls. An inspection of this figure shows also that the excess total temperature near the end walls increases in magnitude and extent as the flow passes through the compressor. Work on methods of predicting annulus wall boundary layers in turbomachines and their effects on performance have been actively pursued in many countries. Horlock (2000) reviewed several approaches to end wall blockage in axial compressors, i.e., Khalid et al. (1999), Smith (1970), Horlock and Perkins (1974). It is worth noting that although these approaches

**FIGURE 5.10**

Traverse Measurements Obtained from a 12-Stage Compressor (Smith, 1970, courtesy of the Elsevier Publishing Co.)

can give estimates of the increase in blockage across a blade row they have now been superseded by advanced computational methods that can simulate multiple stages of compressor with tip clearance flows and other leakage paths.

Example 5.3

The last stage of a low speed axial flow compressor has a reaction of 50% at the design operating point. The design was tested as a cascade of circular arc camber line blades at a space–chord ratio of 0.9, a blade inlet angle of 44.5° , and a blade outlet angle of -0.5° . The nominal deflection of the cascade was measured as $\varepsilon^* = 30^\circ$. The blade height–chord ratio is 2.0 and the work done factor can be taken as 0.86. At the operating condition of interest the mean radius relative incidence $(i - i^*)/\varepsilon^*$ is 0.4 and the corresponding deflection is 37.5° .

For this operating condition, determine

- (i) the nominal incidence i^* ;
- (ii) the inlet and outlet flow angles for the rotor;
- (iii) the flow coefficient and stage loading factor.

In the solution given here the *relative flow* onto the rotor is considered. The notation used for flow angles is the same as for Figure 5.2. For blade angles, β' is therefore used instead of α' for the sake of consistency.

Solution

- (i) The nominal deviation is found using eqns. (3.43) and (3.44). With the camber $\theta = \beta'_1 - \beta'_2 = 44.5^\circ - (-0.5^\circ) = 45^\circ$ and the space-chord ratio, $s/l = 0.9$, then

$$\delta^* = [0.23 + \beta_2^*/500] \theta (s/l)^{1/2}$$

$$\beta_2^* = \delta^* + \beta'_2 = \delta^* - 0.5$$

Therefore,

$$\delta^* = [0.23 + (\delta^* + \beta'_2)/500] \times 45 \times (0.9)^{1/2} = [0.229 + \delta/500] \times 42.69 = 9.776 + 0.0854 \delta^*;$$

hence,

$$\delta^* = 10.69^\circ$$

and

$$\beta_2^* = \delta^* + \beta'_2 = 10.69 - 0.5 = 10.2^\circ.$$

Using $\varepsilon^* = 30^\circ$ the nominal incidence is

$$i^* = \beta_2^* + \varepsilon^* - \beta'_1 = 10.2 + 30 - 44.5 = -4.3^\circ.$$

- (ii) At the operating point $i = 0.4\varepsilon^* + i^* = 7.7^\circ$. Thus, the actual inlet flow angle is

$$\beta_1 = \beta'_1 + i = 52.2^\circ.$$

If the deflection $\varepsilon = 37.5^\circ$ then the flow outlet angle is

$$\beta_2 = \beta_1 - \varepsilon = 14.7^\circ.$$

- (iii) From Figure 5.2, $U = c_{x1}(\tan \alpha_1 + \tan \beta_1) = c_{x2}(\tan \alpha_2 + \tan \beta_2)$. For $c_x = \text{constant}$ across the stage and $R = 0.5$,

$$\beta_1 = \alpha_2 = 52.2^\circ \text{ and } \beta_2 = \alpha_1 = 14.7^\circ$$

and the flow coefficient is

$$\phi = \frac{c_x}{U} = \frac{1}{\tan \alpha_1 + \tan \beta_1} = 0.644.$$

The stage loading factor, $\psi = \Delta h_0 / U^2 = \lambda \phi (\tan \alpha_2 - \tan \alpha_1)$ using eqn. (5.26). Thus, with $\lambda = 0.86$,

$$\psi = 0.568.$$

Stage Matching and Off-Design Operation

Suppose that, for a known operating condition, the performance of a multi-stage compressor is required. Given the blade speed and inlet flow conditions, the performance of the first stage can be determined using its single-stage performance characteristics. This enables the inlet conditions to

the second stage to be determined, which can be used to determine its operating point and performance. The process can be repeated throughout a multi-stage compressor to build up the overall performance characteristics. This approach is known as *stage stacking* and various automated methods have been developed for this purpose, e.g., Howell and Calvert (1978). These methods require single-stage characteristics for each of the stages, which can be derived from measured single-stage characteristics or from empirical correlations based on the mean-line analysis of the individual compressor stages, as done by Wright and Miller (1991).

Estimation of the compressor surge margin is critical, but the prediction of when a multi-stage compressor becomes unstable remains notoriously difficult. In the preliminary design phase, the performance of similar machines can be used for calibration. For example, if a similar design of compressor stage was found to stall when the diffusion factor exceeded 0.6, then this diffusion factor value could be used to estimate where stall occurs in the new design. Within the stage stacking methods, the stall conditions of the individual stages are used to determine the stall margin of the overall machine. However, this approach is problematic since in practice part of a compressor can be stalled when overall the compressor operation is stable.

It is essential for multi-stage compressors to operate satisfactorily at part speed, for example during startup or at low power settings. This situation is complicated in a multi-stage machine because different stages in the compressor operate at different conditions simultaneously. The front stages of the compressor will tend to operate towards stall at part speed because the mass flow rate is reduced and the incidence of the flow onto the rotor blades increased. Rear stages, on the other hand, tend to operate towards choke because the annulus area decrease that occurs through the compressor is specified for the design pressure ratio. At part speed, when the pressure ratio is low, the density in the rear stages is also low, leading to high axial velocity relative to the design condition and possible choking. This variation in operating point between the front and rear stages is described as a stage matching problem. It can be relieved by bleeding off some air from the middle stages or by using variable stator blades to correct the incidence onto the rotor blades in the front stages.

5.10 HIGH MACH NUMBER COMPRESSOR STAGES

As introduced in Chapter 3, the performance of compressor blades deteriorate once the relative inlet Mach number exceeds about 0.7, because the relative Mach numbers within the blade passages exceeds unity and extra losses are generated by shock waves and thicker boundary layers. Furthermore, high Mach numbers reduce the operating range of a compressor because the flow becomes more sensitive to changes in inlet angle.

However, there are two key advantages of high Mach number compressor stages. Firstly, high relative Mach numbers in a compressor imply a high mass flow per unit area, which leads to a more compact (lower diameter) machine for a given mass flow. Secondly, high Mach numbers are caused by high blade speeds, which enable greater work input to the flow and, hence, higher pressure ratios. Using the definitions of stage loading and polytropic efficiency, the stage pressure ratio for a compressor can be written as

$$\frac{p_{03}}{p_{01}} = \left[\frac{\psi U^2}{C_p T_{01}} + 1 \right]^{m_p/(\gamma-1)} . \quad (5.27)$$

This shows that high stage pressure ratios can be achieved by high blade speeds combined with high stage loading and efficiency. In modern transonic compressors, rotor inlet relative Mach numbers of up to 1.7 are now used and single-stage pressure ratios greater than 2 are possible.

Calvert and Ginder (1999) detail the design of transonic compressor stages. They also describe the evolution of modern transonic compressors and the major advances that have been made. Transonic compressor stages are currently used within the single-stage fans of high bypass ratio jet engines, in multi-stage fans within low bypass ratio engines and in the front stages of multi-stage compressors. The fan of a civil jet engine is a particularly important component as it produces over 80% of the thrust of a modern civil aircraft engine. High mass flow per unit area is needed to minimise the engine size, and inlet relative Mach numbers are around 1.4 at the tip. Polytropic efficiencies above 90% are typical and current design pressure ratios are between 1.6 and 1.8.

To alleviate the effects of high relative Mach numbers in transonic compressors, very thin blades are used to reduce their blockage and typically the thickness-to-chord ratio of the blades is only a few percent. In addition, to reduce the peak Mach number on the blade surface, the blades have very low camber, with only a few degrees of turning. As a result, the blade sections towards the tip of a high speed compressor resemble sharp, thin, and almost flat plates.

Figure 5.11 shows the flow pattern within a high speed compressor rotor blade with a supersonic inlet relative Mach number. As the operating point of the compressor changes, the position of the passage shock varies. When the flow is fully choked, the shock moves rearward so that it is fully swallowed within the blade passage. At lower mass flow rates, when the compressor is closer to stall, the shock structure is expelled from the front of the blade passage. The operating point corresponding to peak efficiency usually occurs when the shock wave is close to the blade leading edge.

It is interesting to understand how the shock pattern in Figure 5.11 leads to a very high work input into the flow passing through the compressor. Consider the velocity triangles at inlet and exit from the compressor rotor. Across the passage shock wave, as drawn in Figure 5.11, the flow does not turn significantly, but the density rises sharply. Hence, the relative velocity downstream of the shock will be much lower than upstream. Assuming the blade speed and relative flow angles are the same at rotor inlet and exit, the velocity triangles show that the turning of the flow in the absolute frame is purely a result of the flow slowing down in the relative frame. In contrast, a low speed compressor rotor achieves a work input to the flow by turning the flow in both the relative and absolute frames of reference. The shock wave leads to a rise in entropy in the flow, but it does not necessarily lead to excessive losses, provided the flow on the blades does not separate. As proven by the high efficiencies demonstrated in transonic compressors, a shock wave can be a highly efficient way to compress flow.

5.11 STALL AND SURGE PHENOMENA IN COMPRESSORS

A noticeable feature of any compressor performance map, such as Figure 2.4, is the *surge line*. This line denotes the limit to stable operation. It can be reached by reducing the mass flow (with a throttle valve) whilst the rotational speed is maintained constant.

When a compressor goes into surge the effects are usually quite dramatic. Generally, an increase in noise level is experienced, indicative of a pulsation of the air flow and of mechanical vibration. Commonly, a small number of predominant frequencies are superimposed on a high background noise. The lowest frequencies are usually associated with what is termed a *Helmholtz-type of resonance* of the

**FIGURE 5.11**

Flow through a Supersonic Compressor Rotor

flow through the machine, with the inlet and/or outlet volumes. The higher frequencies are known to be due to *rotating stall* and are of the same order as the rotational speed of the impeller.

Rotating stall is another phenomenon of axial compressor flow and has been the subject of many detailed experimental and theoretical investigations. An early detailed survey of the phenomenon was given by Emmons, Kronauer, and Rocket (1959). Briefly, when a blade row (usually the rotor of a compressor) reaches the “stall point,” the blades, instead of all stalling together as might be expected, stall in separate patches and these stall patches, moreover, travel around the compressor annulus (i.e., they rotate).

That stall patches *must* propagate from blade to blade has a simple physical explanation. Consider a portion of a blade row, as illustrated in Figure 5.12, to be affected by a stall patch. This patch must cause a partial obstruction to the flow that is deflected on both sides of it. Thus, the incidence of the flow onto the blades on the right of the stall cell is reduced, but the incidence to the left is increased. As these blades are already close to stalling, the net effect is for the stall patch to move to the left; the motion is then self-sustaining.

**FIGURE 5.12**

Model Illustrating Mechanism of Stall Cell Propagation: Partial Blockage Due to Stall Patch Deflects Flow, Increasing Incidence to the Left and Decreasing Incidence to the Right

There is a strong practical reason for the wide interest in rotating stall. Stall patches travelling around blade rows load and unload each blade at some frequency related to the speed and number of the patches. This frequency may be close to a natural frequency of blade vibration and there is clearly a need for accurate prediction of the conditions producing such a vibration. Several cases of blade failure due to resonance induced by rotating stall have been reported, usually with serious consequences to the whole compressor.

It is possible to distinguish between surge and propagating stall by the unsteadiness, or otherwise, of the total mass flow. The characteristic of stall propagation is that the flow passing through the annulus, summed over the whole area, is steady with time; the stall cells merely redistribute the flow over the annulus. Surge, on the other hand, involves an axial oscillation of the total mass flow, a condition highly detrimental to efficient compressor operation.

The point a compressor enters stall or surge still cannot be predicted reliably, even with the most advanced computational methods. However, the understanding of the mechanisms leading to stall and surge have been improved significantly through extensive research.

One early physical explanation of the breakdown of the flow in a compressor is given by Horlock (1958). Figure 5.13 shows a constant rotor speed compressor characteristic (C) of pressure ratio plotted against flow coefficient. A second set of curves (T_1 , T_2 , etc.) are superimposed on this figure showing the pressure loss characteristics of the throttle for various fixed throttle positions. The intersection of curves T with compressor curve C denotes the various operating points of the combination. A state of *flow stability* exists if the throttle curves at the point of intersection have a greater (positive) slope than the compressor curve. That this is so may be illustrated as follows. Consider the operating point at the intersection of T_2 with C . If a small reduction of flow should momentarily occur, the compressor will produce a greater pressure rise and the throttle resistance will fall. The flow rate must, of necessity, increase so that the original operating point is restored. A similar argument holds if the flow is temporarily augmented, so that the flow is completely stable at this operating condition.

If, now, the operating point is at point U , unstable operation is possible. A small reduction in flow will cause a greater reduction in compressor pressure ratio than the corresponding pressure ratio across the throttle. As a consequence of the increased resistance of the throttle, the flow will decrease even further and the operating point U is clearly unstable. By inference, neutral stability exists when the slopes of the throttle pressure loss curves equal the compressor pressure rise curve.

**FIGURE 5.13**

Stability of Operation of a Compressor (adapted from Horlock, 1958)

Tests on low pressure ratio compressors appear to substantiate this explanation of instability. However, for high rotational speed multi-stage compressors this argument does not seem sufficient to describe surging. With high speeds no stable operation appears possible on constant speed curves of positive slope and surge appears to occur when this slope is zero or even a little negative. A more complete understanding of surge in multi-stage compressors is possible only from a detailed study of the individual stages' performance and their interaction with one another.

Casing Treatment

It was discovered in the late 1960s that the stall of a compressor could be delayed to a lower mass flow by a suitable treatment of the compressor casing. Given the right conditions this can be of great benefit in extending the range of stall-free operation. Numerous investigations have since been carried out on different types of casing configurations under widely varying flow conditions to demonstrate the range of usefulness of the treatment.

Greitzer et al. (1979) observed that two types of stall could be found in a compressor blade row, namely, "blade stall" and "wall stall." Blade stall is, roughly speaking, a two-dimensional type of stall where a significant part of the blade has a large wake leaving the blade suction surface. Wall stall is a stall connected with the boundary layer on the outer casing. Figure 5.14 illustrates the two types of stall. Greitzer et al. found that the response to casing treatment depended conspicuously upon the type of stall encountered.

The influence of a grooved casing treatment on the stall margin of a model axial compressor rotor was investigated experimentally. Two rotor builds of different blade solidities, σ (chord-space ratio), but with all the other parameters identical were tested. Greitzer et al. emphasised that the motive behind the use of different solidities was simply a convenient way to change the type of stall from a blade stall to a wall stall and that the benefit of casing treatment was unrelated to the amount of solidity of the blade row. The position of the casing treatment insert in relation to the rotor blade row is shown in Figure 5.15(a) and the appearance of the grooved surface used is illustrated in Figure 5.15(b). The grooves, described as "axial skewed" and extending over the middle 44% of the blade, have been used in a wide variety of compressors.

FIGURE 5.14

Compressor Stall Inception (adapted from Greitzer et al., 1979)

FIGURE 5.15

Position and Appearance of Casing Treatment Insert (adapted from Greitzer et al., 1979)

**FIGURE 5.16**

Effects of Casing Treatment and Solidity on Compressor Characteristics (adapted from Greitzer et al., 1979, and data points removed for clarity)

As predicted from their design study, the high solidity blading ($\sigma = 2$) resulted in the production of a wall stall, while the low solidity ($\sigma = 1$) blading gave a blade stall. Figure 5.16 shows the results obtained for the four conditions tested. The most important difference in performance is the change in the stall point with and without the casing treatment. It can be seen that with the grooved casing a substantial change in the range of ϕ occurred with the high solidity blading. However, for the low solidity blading there is only a marginal difference in range. The shape of the performance curve is also significantly affected for the high solidity rotor blades, with a substantial increase in the peak pressure rise brought about by the grooved casing treatment.

Casing treatment has not been widely adopted in the aircraft engine industry because of the efficiency penalty that it often causes. Smith and Cumpsty (1984) made an extensive series of experimental investigations to try to discover the cause for this loss in compressor efficiency. At the simplest level it was realised that the slots provide a route for fluid to pass from the pressure surface to the suction surface allowing a small proportion of the flow to be recirculated. The approaching boundary layer fluid tends to have a high absolute swirl and is, therefore, suitably orientated to enter the slots. Normally, with a smooth wall the high swirl would cause energy to be wasted but, with the casing treatment, the flow entering the slot is turned and reintroduced back into the main flow near the blade's leading edge with its absolute swirl direction reversed. The re-entrant flow has, in effect, flowed upstream along the slot to a lower pressure region.

Control of Flow Instabilities

Important and dramatic advances have been made in recent years in the understanding and controlling of surge and rotating stall. Both phenomena are now regarded as the mature forms of the natural oscillatory modes of the compression system (see Moore and Greizer, 1986). The flow model they considered predicts that an initial disturbance starts with a very small amplitude but quickly grows into a large amplitude form. Thus, the stability of the compressor is equivalent to the stability of these small amplitude waves that exist just prior to stall or surge (Haynes, Hendricks, and Epstein, 1994). Only a few of the many papers written on the understanding of these unstable flows and the application of control to suppress instability are cited here.

Epstein, Ffowcs Williams, and Greitzer. (1989) first suggested that surge and rotating stall could be prevented by using active feedback control to damp the hydrodynamic disturbances while they were still of small amplitude. Active suppression of surge was subsequently demonstrated on a centrifugal compressor by Ffowcs Williams and Huang (1989), also by Pinsley et al. (1991) and on an axial compressor by Day (1993). Shortly after this Paduano et al. (1993) demonstrated active suppression of rotating stall in a single-stage low speed axial compressor. By damping the small amplitude waves rotating about the annulus prior to stall, they increased the stable flow range of the compressor by 25%. The control scheme adopted comprised a circumferential array of hot wires just upstream of the compressor and a set of 12 individually actuated vanes upstream of the rotor used to generate the rotating disturbance structure required for control. Haynes et al. (1994), using the same control scheme as Paduano et al., actively stabilised a three-stage, low speed axial compressor and obtained an 8% increase in the operating flow range. Gysling and Greitzer (1995) employed a different strategy using aeromechanical feedback to suppress the onset of rotating stall in a low speed axial compressor.

Further methods of active and passive control to prevent stall or surge continue to be extensively researched and new technologies, such as micro devices, are being applied to this purpose. However, there is still very limited adoption of control within commercially available compressors and even casing treatment is used in only a few jet engine compressor designs. Further application of these technologies in the future will be realised only if their robustness and reliability can match that of existing compressor components.

5.12 LOW SPEED DUCTED FANS

In essence, these widely used fans are simply single-stage compressors with a low pressure (and temperature) rise, so that much of the foregoing theory of this chapter is valid for this class of machine. However, because of the high space–chord ratio used in many of these fans, a simplified theoretical approach based on *isolated aerofoil theory* is often used. This method can be of use in the design of ventilating fans in which aerodynamic interference between adjacent blades can be assumed negligible. Attempts have been made to extend the scope of isolated aerofoil theory to less widely spaced blades by the introduction of an *interference factor*; for instance, the ratio k of the lift force of a single blade in a cascade to the lift force of a single isolated blade. As a guide to the degree of this interference, an exact mathematical solution obtained by Weinig (1935) and used by Wislicenus (1947) for a row of thin flat plates is of value and is shown in Figure 5.17. This illustrates the dependence of k on space–chord ratio for several stagger angles. The rather pronounced effect of stagger for moderate space–chord ratios should be noted as well as the asymptotic convergence of k towards unity for higher space–chord ratios.

Two simple types of axial-flow fan are shown in Figure 5.18 in which the inlet and outlet flows are entirely axial. In the first type (a), a set of guide vanes provides a contra-swirl and the flow is restored to the axial direction by the rotor. In the second type (b), the rotor imparts swirl in the direction of blade motion and the flow is restored to the axial direction by the action of outlet *straighteners* (or outlet guide vanes). The theory and design of both these types of fan have been investigated by Van Niekerk (1958) who was able to formulate expressions for calculating the optimum sizes and fan speeds using blade element theory.

Note that the analysis in this section uses cartesian (x and y) coordinates in order to be consistent with the low-speed cascade analysis presented in Section 3.4.

FIGURE 5.17

Weinig's Results for Lift Ratio of a Cascade of Thin Flat Plates, Showing Dependence on Stagger Angle and Space-Chord Ratio (adapted from Wislicenus, 1947)

Lift and Drag Coefficients

For a low speed fan the stage loading factor may be expressed in terms of the lift and drag coefficients for the *rotor*. From Figure 3.12, replacing α_m with β_m , the tangential blade force on the *moving* blades per unit span is

$$Y = L \cos \beta_m + D \sin \beta_m = L \cos \beta_m \left(1 + \frac{C_D}{C_L} \tan \beta_m \right),$$

where $\tan \beta_m = \frac{1}{2}(\tan \beta_1 + \tan \beta_2)$.

Now $C_L = L / \left(\frac{1}{2} \rho w_m^2 l \right)$; hence, substituting for L ,

$$Y = \frac{1}{2} \rho c_x^2 l C_L \sec \beta_m (1 + \tan \beta_m C_D / C_L). \quad (5.28)$$

The work done by *each* moving blade per second is YU and is transferred to the fluid through *one* blade passage during that period. Thus, $YU = \rho s c_x (h_{03} - h_{01})$.

Therefore, the stage loading factor may now be written

$$\psi = \frac{h_{03} - h_{01}}{U^2} = \frac{Y}{\rho s c_x U}. \quad (5.29)$$

Substituting eqn. (5.28) in eqn. (5.29) the final result is

$$\psi = (\phi/2) \sec \beta_m (l/s) (C_L + C_D \tan \beta_m). \quad (5.30)$$

**FIGURE 5.18**

Two Simple Types of Axial-Flow Fan and Their Associated Velocity Diagrams (after Van Niekerk, 1958)

In Chapter 3, the approximate analysis indicated that maximum efficiency is obtained when the mean flow angle is 45° . The corresponding optimum stage loading factor at $\beta_m = 45^\circ$ is

$$\psi_{\text{opt}} = (\phi/\sqrt{2}(l/s)(C_L + C_D). \quad (5.31)$$

Since $C_D \ll C_L$ in the normal low loss operating range, it is permissible to drop C_D from eqn. (5.31).

5.13 BLADE ELEMENT THEORY

A blade element at a given radius can be defined as an aerofoil of vanishingly small span. In fan design theory it is commonly assumed that each such element operates as a two-dimensional aerofoil, behaving completely independently of conditions at any other radius. Now the forces impressed upon the fluid by unit span of a single stationary blade have been considered in some detail already, in Chapter 3. Considering an *element of a rotor blade* dr , at radius r , the elementary axial and tangential forces, dX and dY , respectively, exerted on the fluid are, referring to Figure 3.12,

$$dX = (L \sin \beta_m - D \cos \beta_m) dr, \quad (5.32)$$

$$dY = (L \cos \beta_m + D \sin \beta_m) dr, \quad (5.33)$$

where $\tan \beta_m = \frac{1}{2} \{ \tan \beta_1 + \tan \beta_2 \}$ and L, D are the lift and drag on unit span of a blade.

Writing $\tan \gamma = D/L = C_D/C_L$,

$$dX = L(\sin \beta_m - \tan \gamma \cos \beta_m) dr.$$

Introducing the lift coefficient $C_L = L / \left(\frac{1}{2} \rho w_m^2 l \right)$ for the rotor blade (cf. eqn. 3.23) into the preceding expression and rearranging,

$$dX = \frac{\rho c_x^2 l C_L dr}{2 \cos^2 \beta_m} \times \frac{\sin(\beta_m - \gamma)}{\cos \gamma}, \quad (5.34)$$

where $c_x = w_m \cos \beta_m$.

The torque exerted by *one* blade element at radius r is $r dY$. If there are Z blades the elementary torque is

$$d\tau = r Z dY = r Z L (\cos \beta_m + \tan \gamma \sin \beta_m) dr,$$

after using eqn. (5.33). Substituting for L and rearranging,

$$d\tau = \frac{\rho c_x^2 l Z C_L r dr}{2 \cos^2 \beta_m} \times \frac{\cos(\beta_m - \gamma)}{\cos \gamma}. \quad (5.35)$$

Now the work done by the rotor in unit time equals the product of the stagnation enthalpy rise and the mass flow rate; for the elementary ring of area $2\pi r dr$,

$$\Omega d\tau = (C_p \Delta T_0) d\dot{m}, \quad (5.36)$$

where Ω is the rotor angular velocity and the element of mass flow, $d\dot{m} = \rho c_x 2\pi r dr$.

Substituting eqn. (5.35) into eqn. (5.36),

$$C_p \Delta T_0 = C_p \Delta T = C_L \frac{U_{C_x} l \cos(\beta_m - \gamma)}{2s \cos^2 \beta_m \cos \gamma}, \quad (5.37)$$

where $s = 2\pi r/Z$. Now the static temperature rise equals the stagnation temperature rise when the velocity is unchanged across the fan; this, in fact, is the case for both types of fan shown in Figure 5.18.

The increase in static pressure of the *whole* of the fluid crossing the rotor row may be found by equating the total axial force on all the blade elements at radius r with the product of static pressure rise and elementary area $2\pi r dr$, or

$$Z dX = (p_2 - p_1) 2\pi r dr.$$

Using eqn. (5.34) and rearranging,

$$p_2 - p_1 = C_L \frac{\rho c_x^2 l \sin(\beta_m - \gamma)}{2s \cos^2 \beta_m \cos \gamma}. \quad (5.38)$$

Note that, so far, all these expressions are applicable to both types of fan shown in Figure 5.17.

5.14 BLADE ELEMENT EFFICIENCY

Consider the fan type shown in Figure 5.18(a) fitted with guide vanes at inlet. The pressure rise across this fan is equal to the rotor pressure rise, $p_2 - p_1$, minus the drop in pressure across the guide vanes, $p_i - p_1$. The ideal pressure rise across the fan is given by the product of density and $C_p \Delta T_0$. Fan designers define a blade element efficiency as

$$\eta_b = \{(p_2 - p_1) - (p_i - p_1)\} / (\rho C_p \Delta T_0). \quad (5.39)$$

The drop in static pressure across the guide vanes, assuming *frictionless* flow for simplicity, is

$$p_i - p_1 = \frac{1}{2} \rho (c_1^2 - c_x^2) = \frac{1}{2} \rho c_{y1}^2. \quad (5.40)$$

Now, since the change in swirl velocity across the rotor is equal and opposite to the swirl produced by the guide vanes, the work done per unit mass flow, $C_p \Delta T_0$ is equal to $U c_{y1}$. Thus, the second term in eqn. (5.39) is

$$(p_i - p_1) / (\rho C_p \Delta T_0) = c_{y1} / (2U). \quad (5.41)$$

Combining eqns. (5.37), (5.38), and (5.41) in eqn. (5.39) then,

$$\eta_b = (c_x / U) \tan(\beta_m - \gamma) - c_{y1} / (2U). \quad (5.42a)$$

The foregoing exercise can be repeated for the second type of fan having outlet straightening vanes, and assuming frictionless flow through the “straighteners,” the rotor blade element efficiency becomes

$$\eta_b = (c_x / U) \tan(\beta_m - \gamma) + c_{y2} / (2U). \quad (5.42b)$$

Some justification for ignoring the losses occurring in the guide vanes is found by observing that the ratio of guide vane pressure change to rotor pressure rise is normally small in ventilating fans. For example, in the first type of fan,

$$(p_i - p_1) / (p_2 - p_1) \div \left(\frac{1}{2} \rho c_{y1}^2 \right) / (\rho U c_{y1}) = c_{y1} / 2(U),$$

the tangential velocity c_{y1} being rather small compared with the blade speed U .

5.15 LIFT COEFFICIENT OF A FAN AEROFOIL

For a specified blade element geometry, blade speed and lift–drag ratio the temperature and pressure rises can be determined if the lift coefficient is known. An estimate of lift coefficient is most easily obtained from two-dimensional aerofoil potential flow theory. Glauert (1959) showed, for isolated aerofoils of small camber and thickness, that

$$C_L = 2\pi \sin \alpha, \quad (5.43a)$$

where α is the angle between the flow direction and *line of zero lift* of the aerofoil. For an isolated, cambered aerofoil Wislicenus (1947) suggested that the zero lift line may be found by joining the trailing edge point with the point of maximum camber, as depicted in Figure 5.19(a). For fan blades experiencing some interference effects from adjacent blades, the modified lift coefficient of a blade may be

**FIGURE 5.19**

Method Suggested by Wislicenus (1947) for Obtaining the Zero Lift Line of Cambered Aerofoils

estimated by assuming that Weinig's results for flat plates (Figure 5.17) are valid for the slightly cambered, finite thickness blades, and

$$C_L = 2\pi k \sin \alpha. \quad (5.43b)$$

When the vanes overlap (as they may do at sections close to the hub), Wislicenus suggested that the zero lift line may be obtained by the line connecting the trailing edge point with the maximum camber of that portion of blade that is not overlapped, Figure 5.19(b).

The extension of both blade element theory and cascade data to the design of complete fans was discussed in considerable detail by Wallis (1961).

PROBLEMS

(Note: In questions 1–4, 6 and 8 take $R = 287 \text{ J/(kg}^\circ\text{C)}$ and $\gamma = 1.4$.)

- An axial flow compressor is required to deliver 50 kg/s of air at a stagnation pressure of 500 kPa. At inlet to the first stage the stagnation pressure is 100 kPa and the stagnation temperature is 23°C. The hub and tip diameters at this location are 0.436 m and 0.728 m. At the mean radius, which is constant through all stages of the compressor, the reaction is 0.50 and the absolute air angle at stator exit is 28.8° for all stages. The speed of the rotor is 8000 rev/min. Determine the number of similar stages needed, assuming that the polytropic efficiency is 0.89 and that the axial velocity at the mean radius is constant through the stages and equal to 1.05 times the average axial velocity.
- Derive an expression for the degree of reaction of an axial compressor stage in terms of the flow angles relative to the rotor and the flow coefficient. Data obtained from early cascade tests suggested that the limit of efficient working of an axial-flow compressor stage occurred when
 - a relative Mach number of 0.7 on the rotor is reached;
 - the flow coefficient is 0.5;
 - the relative flow angle at rotor outlet is 30° measured from the axial direction;
 - the stage reaction is 50%.
 Find the limiting stagnation temperature rise obtained in the first stage of an axial compressor working under these conditions and compressing air at an inlet stagnation temperature of 289 K. Assume the axial velocity is constant across the stage.
- Each stage of an axial flow compressor is of 0.5 reaction and has the same mean blade speed and the same flow outlet angle of 30° relative to the blades. The mean flow coefficient is constant for all stages at 0.5. At entry to the first stage the stagnation temperature is 278 K, the stagnation pressure 101.3 kPa, the static pressure is 87.3 kPa, and the flow area 0.372 m². Using compressible flow analysis determine the axial velocity and the mass flow rate. Determine also the shaft power needed to drive the compressor when there are six stages and the mechanical efficiency is 0.99.

4. A 16-stage axial flow compressor is to have a pressure ratio of 6.3. Tests have shown that a stage total-to-total efficiency of 0.9 can be obtained for each of the first six stages and 0.89 for each of the remaining 10 stages. Assuming constant work done in each stage and similar stages find the compressor overall total-to-total efficiency. For a mass flow rate of 40 kg/s determine the power required by the compressor. Assume an inlet total temperature of 288 K.
5. At a particular operating condition an axial flow compressor has a reaction of 0.6, a flow coefficient of 0.5, and a stage loading, defined as $\Delta h_0/U^2$ of 0.35. If the flow exit angles for each blade row may be assumed to remain unchanged when the mass flow is throttled, determine the reaction of the stage and the stage loading when the air flow is reduced by 10% at constant blade speed. Sketch the velocity triangles for the two conditions. Comment upon the likely behaviour of the flow when further reductions in air mass flow are made.
6. A high-pressure axial compressor for a jet engine rotates at 15,000 rpm with an overall stagnation pressure ratio of 8.5. The mass flow rate of air through the compressor is 16 kg/s^{-1} and the stagnation conditions at inlet are 200 kPa and 450 K. The polytropic efficiency is 91%.
 - (a) If the mean radius is 0.24 m and this is constant throughout the compressor, calculate the total-to-total isentropic efficiency of the compressor and show that, for the stage loading to be less than 0.4 in all stages, eight stages are required.
 - (b) The compressor is designed with repeating stages and zero inlet swirl. If the inlet axial Mach number is 0.52, calculate the mean flow coefficient and sketch the velocity triangles for one stage. Show that the blade height at exit from the compressor is about 7.8 mm.
7. The preliminary design of an axial flow compressor is to be based upon a simplified consideration of the mean diameter conditions. Suppose that the stage characteristics of a repeating stage of such a design are as follows:

Stagnation temperature rise	25°C
Reaction ratio	0.6
Flow coefficient	0.5
Blade speed	275 m/s

The gas compressed is air with a specific heat at constant pressure of $1.005 \text{ kJ/(kg}^\circ\text{C)}$. Assuming constant axial velocity across the stage and equal absolute velocities at inlet and outlet, determine the relative flow angles for the rotor. Physical limitations for this compressor dictate that the space-chord ratio is unity at the mean diameter. Using Howell's correlation method, determine a suitable camber at the midheight of the rotor blades given that the incidence angle is zero. Use the tangent difference approximation,

$$\tan \beta_1^* - \tan \beta_2^* = 1.55/(1 + 1.5s/l),$$

for nominal conditions and the data of Figure 3.16 for finding the design deflection. (Hint: Use several trial values of θ to complete the solution.)

8. Air enters an axial flow compressor with a stagnation pressure and temperature of 100 kPa and 293 K, leaving at a stagnation pressure of 600 kPa. The hub and tip diameters at entry to the first stage are 0.3 m and 0.5 m. The flow Mach number *after* the inlet guide vanes is 0.7 at the mean

diameter (0.4 m). At this diameter, which can be assumed constant for all the compressor stages, the reaction is 50%, the axial velocity to mean blade speed ratio is 0.6, and the absolute flow angle is 30° at the exit from all stators. The type of blading used for this compressor is designated “free vortex” and the axial velocity is constant for each stage. Assuming isentropic flow through the inlet guide vanes (IGVs) and a small stage efficiency of 0.88, determine

- (i) the air velocity at exit from the IGVs at the mean radius;
- (ii) the air mass flow and rotational speed of the compressor;
- (iii) the specific work done in each stage;
- (iv) the overall efficiency of the compressor;
- (v) the number of compressor stages required and the power needed to drive the compressor;
- (vi) consider the implications of rounding the number of stages to an integer value if the pressure ratio *must* be maintained at 6 for the same values of blade speed and flow coefficient.

Note: In the following problems on axial-flow fans the medium is air for which the density is taken to be 1.2 kg/m^3 .

9. (a) The volume flow rate through an axial-flow fan fitted with inlet guide vanes is $2.5 \text{ m}^3/\text{s}$ and the rotational speed of the rotor is 2604 rev/min. The rotor blade tip radius is 23 cm and the root radius is 10 cm. Given that the stage static pressure increase is 325 Pa and the blade element efficiency is 0.80, determine the angle of the flow leaving the guide vanes at the tip, mean, and root radii.
 (b) A diffuser is fitted at exit to the fan with an area ratio of 2.5 and an effectiveness of 0.82. Determine the overall increase in static pressure and the air velocity at diffuser exit.
10. The rotational speed of a four-bladed axial-flow fan is 2900 rev/min. At the mean radius of 16.5 cm the rotor blades operate at $C_L = 0.8$ with $C_D = 0.045$. The inlet guide vanes produce a flow angle of 20° to the axial direction and the axial velocity through the stage is constant at 20 m/s. For the mean radius, determine
 - (i) the rotor relative flow angles;
 - (ii) the stage efficiency;
 - (iii) the rotor static pressure increase;
 - (iv) the size of the blade chord needed for this duty.
11. A diffuser, fitted to the axial fan in the previous problem, has an efficiency of 70% and an area ratio of 2.4. Assuming that the flow at entry to the diffuser is uniform and axial in direction, and the losses in the entry section and the guide vanes are negligible, determine
 - (i) the static pressure rise and the pressure recovery factor of the diffuser;
 - (ii) the loss in total pressure in the diffuser;
 - (iii) the overall efficiency of the fan and diffuser.

Three-Dimensional Flows in Axial Turbomachines

It cost much labour and many days before all these things were brought to perfection.

Defoe, Robinson Crusoe

6.1 INTRODUCTION

In Chapters 4 and 5 the fluid motion through the blade rows of axial turbomachines was assumed to be two-dimensional in the sense that radial (i.e., spanwise) velocities did not exist. This assumption is not unreasonable for axial turbomachines of high hub–tip ratio. However, with hub–tip ratios less than about 4/5, radial velocities through a blade row may become appreciable, the consequent redistribution of mass flow (with respect to radius) seriously affecting the outlet velocity profile (and flow angle distribution). The temporary imbalance between the strong centrifugal forces exerted on the fluid and radial pressures restoring equilibrium is responsible for these radial flows. Thus, to an observer travelling with a fluid particle, radial motion will continue until sufficient fluid is transported (radially) to change the pressure distribution to that necessary for equilibrium. The flow in an annular passage in which there is no radial component of velocity, whose streamlines lie in circular, cylindrical surfaces and which is axisymmetric, is commonly known as *radial equilibrium* flow.

An analysis called *the radial equilibrium method*, widely used for three-dimensional design calculations in axial compressors and turbines, is based upon the assumption that any radial flow that may occur is completed *within* a blade row, the flow *outside* the row then being in radial equilibrium. Figure 6.1 illustrates the nature of this assumption. The other assumption, that the flow is axisymmetric, implies that the effect of the discrete blades is not transmitted to the flow.

6.2 THEORY OF RADIAL EQUILIBRIUM

Consider a small element of fluid of mass dm , shown in Figure 6.2, of unit depth and subtending an angle $d\theta$ at the axis, rotating about the axis with tangential velocity, c_θ at radius r . The element is in radial equilibrium so that the pressure forces balance the centrifugal forces:

$$(p + dp)(r + dr)d\theta - prd\theta - \left(p + \frac{1}{2}dp\right)drd\theta = dmc_\theta^2/r.$$

Writing $dm = \rho r d\theta dr$ and ignoring terms of the second order of smallness this equation reduces to

$$\frac{1}{\rho} \frac{dp}{dr} = \frac{c_\theta^2}{r}. \quad (6.1)$$

FIGURE 6.1

Radial Equilibrium Flow Through a Rotor Blade Row

FIGURE 6.2

Fluid Element in Radial Equilibrium ($c_r = 0$)

If the swirl velocity c_θ and density are known functions of the radius, the radial pressure variation along the blade length can be determined:

$$p_{\text{tip}} - p_{\text{root}} = \int_{\text{root}}^{\text{tip}} \rho c_\theta^2 \frac{dr}{r}. \quad (6.2a)$$

For an incompressible fluid,

$$p_{\text{tip}} - p_{\text{root}} = \rho \int_{\text{root}}^{\text{tip}} c_\theta^2 \frac{dr}{r}. \quad (6.2b)$$

The stagnation enthalpy is written (with $c_r = 0$)

$$h_0 = h + \frac{1}{2}(c_x^2 + c_\theta^2); \quad (6.3)$$

therefore,

$$\frac{dh_0}{dr} = \frac{dh}{dr} + c_x \frac{dc_x}{dr} + c_\theta \frac{dc_\theta}{dr}. \quad (6.4)$$

The thermodynamic relation $Tds = dh - (1/\rho)dp$ can be similarly written

$$T \frac{ds}{dr} = \frac{dh}{dr} - \frac{1}{\rho} \frac{dp}{dr}. \quad (6.5)$$

Combining eqns. (6.1), (6.4), and (6.5), eliminating dp/dr and dh/dr , the *radial equilibrium equation* may be obtained:

$$\frac{dh_0}{dr} - T \frac{ds}{dr} = c_x \frac{dc_x}{dr} + \frac{c_\theta}{r} \frac{d}{dr}(rc_\theta). \quad (6.6a)$$

If the stagnation enthalpy h_0 and entropy s remain the same at all radii, $dh_0/dr = ds/dr = 0$, eqn. (6.6a) becomes

$$c_x \frac{dc_x}{dr} + \frac{c_\theta}{r} \frac{d}{dr}(rc_\theta) = 0. \quad (6.6b)$$

Equation (6.6b) will hold for the flow between the rows of an adiabatic, reversible (ideal) turbomachine in which rotor rows either deliver or receive equal work at all radii. Now if the flow is incompressible, instead of eqn. (6.3) use $p_0 = p + \frac{1}{2}\rho(c_x^2 + c_\theta^2)$ to obtain

$$\frac{1}{\rho} \frac{dp_0}{dr} = \frac{1}{\rho} \frac{dp}{dr} + c_x \frac{dc_x}{dr} + c_\theta \frac{dc_\theta}{dr}. \quad (6.7)$$

Combining eqns. (6.1) and (6.7),

$$\frac{1}{\rho} \frac{dp_0}{dr} = c_x \frac{dc_x}{dr} + \frac{c_\theta}{r} \frac{d}{dr}(rc_\theta). \quad (6.8)$$

Equation (6.8) clearly reduces to eqn. (6.6b) in a turbomachine in which equal work is delivered at all radii and the total pressure losses across a row are uniform with radius.

Equation (6.6b) may be applied to two sorts of problem: the design (or indirect) problem, in which the tangential velocity distribution is specified and the axial velocity variation is found, or the direct problem, in which the swirl angle distribution is specified, the axial and tangential velocities being determined.

6.3 THE INDIRECT PROBLEM

Free-Vortex Flow

This is a flow where the product of radius and tangential velocity remains constant (i.e., $rc_\theta = K$, a constant). The term *vortex free* might be more appropriate as the vorticity (to be precise we mean *axial* vorticity component) is then zero.

Consider an element of an ideal inviscid fluid rotating about some fixed axis, as indicated in Figure 6.3. The *circulation* Γ is defined as the line integral of velocity around a curve enclosing an area A , or $\Gamma = \oint c ds$. The *vorticity* at a point is defined as the limiting value of circulation $\delta\Gamma$ divided by area δA , as δA becomes vanishingly small. Thus, vorticity, $\omega = d\Gamma/dA$.

**FIGURE 6.3**

Circulation About an Element of Fluid

For the element shown in Figure 6.3, $c_r = 0$ and

$$d\Gamma = (c_\theta + dc_\theta)(r + dr)d\theta - c_\theta r d\theta = \left(\frac{dc_\theta}{dr} + \frac{c_\theta}{r} \right) r dr d\theta,$$

ignoring the product of small terms. Thus, $\omega = d\Gamma/dA = (1/r)d(rc_\theta)/dr$. If the vorticity is zero, $d(rc_\theta)/dr$ is also zero and, therefore, rc_θ is constant with radius.

Putting $rc_\theta = \text{constant}$ in eqn. (6.6b), then $dc_x/dr = 0$ and so $c_x = a$ constant. This information can be applied to the incompressible flow through a free-vortex compressor or turbine stage, enabling the radial variation in flow angles, reaction and work to be found.

Compressor Stage

Consider the case of a compressor stage in which $rc_{\theta 1} = K_1$ before the rotor and $rc_{\theta 2} = K_2$ after the rotor, where K_1 and K_2 are constants. The work done by the rotor on unit mass of fluid is

$$\Delta W = U(c_{\theta 2} - c_{\theta 1}) = \Omega r(K_2/r - K_1/r) = \text{constant}.$$

Thus, the work done is equal at all radii.

The relative flow angles (see Figure 5.2) entering and leaving the rotor are

$$\tan \beta_1 = \frac{U}{c_x} - \tan \alpha_1 = \frac{\Omega r - K_1/r}{c_x},$$

$$\tan \beta_2 = \frac{U}{c_x} - \tan \alpha_2 = \frac{\Omega r - K_2/r}{c_x}.$$

in which $c_{x1} = c_{x2} = c_x$ for incompressible flow.

In Chapter 5, reaction in an axial compressor is defined by

$$R = \frac{\text{static enthalpy rise in the rotor}}{\text{static enthalpy rise in the stage}}.$$

For a normal stage ($\alpha_1 = \alpha_3$) with c_x constant across the stage, the reaction was shown to be

$$R = \frac{c_x}{2U} (\tan \beta_1 + \tan \beta_2). \quad (5.21)$$

Substituting values of $\tan \beta_1$ and $\tan \beta_2$ into eqn. (5.21), the reaction becomes

$$R = 1 - \frac{k}{r^2}, \quad (6.9)$$

where

$$k = (K_1 + K_2)/(2\Omega).$$

It will be clear that, as k is positive, the reaction increases from root to tip. Likewise, from eqn. (6.1) we observe that as c_θ^2/r is always positive (excepting $c_\theta = 0$), so static pressure increases from root to tip. For the free-vortex flow $rc_\theta = K$, the static pressure variation can be shown to be $p/\rho = \text{constant} - K^2/(2r^2)$ upon integrating eqn. (6.1).

Example 6.1

An axial flow compressor stage is designed to give free-vortex tangential velocity distributions for all radii before and after the rotor blade row. The tip diameter is constant and 1.0 m; the hub diameter is 0.9 m and constant for the stage. At the rotor tip the flow angles are as follows:

- Absolute inlet angle, $\alpha_1 = 30^\circ$;
- Relative inlet angle, $\beta_1 = 60^\circ$;
- Absolute outlet angle, $\alpha_2 = 60^\circ$;
- Relative outlet angle, $\beta_2 = 30^\circ$.

Determine

- (i) the axial velocity;
- (ii) the mass flow rate;
- (iii) the power absorbed by the stage;
- (iv) the flow angles at the hub;
- (v) the reaction ratio of the stage at the hub;

given that the rotational speed of the rotor is 6000 rev/min and the gas density is 1.5 kg/m^3 , which can be assumed constant for the stage. It can be further assumed that stagnation enthalpy and entropy are constant before and after the rotor row for the purpose of simplifying the calculations.

Solution

- (i) The rotational speed, $\Omega = 2\pi N/60 = 628.4 \text{ rad/s}$. Therefore, blade tip speed, $U_t = \Omega r_t = 314.2 \text{ m/s}$, and blade speed at hub, $U_h = \Omega r_h = 282.5 \text{ m/s}$. From the velocity diagram for the stage (e.g., Figure 5.2), the blade tip speed is

$$U_t = c_x (\tan 60^\circ + \tan 60^\circ) = c_x (\sqrt{3} + 1/\sqrt{3}).$$

Therefore, $c_x = 136$ m/s, constant at all radii by eqn. (6.6b).

- (ii) The rate of mass flow, $\dot{m} = \pi(r_t^2 - r_h^2)\rho c_x = \pi(0.5^2 - 0.45^2)1.5 \times 136 = 30.4$ kg/s.
 (iii) The power absorbed by the stage,

$$\begin{aligned}\dot{W}_c &= \dot{m}U_t(c_{\theta 2t} - c_{\theta 1t}) \\ &= \dot{m}U_t c_x (\tan \alpha_{2t} - \tan \alpha_{1t}) \\ &= 30.4 \times 314.2 \times 136(\sqrt{3} - 1/\sqrt{3}) \\ &= 1.5 \text{ MW}.\end{aligned}$$

- (iv) At inlet to the rotor tip,

$$c_{\theta 1t} = c_x \tan \alpha_1 = 136/\sqrt{3} = 78.6 \text{ m/s}.$$

The absolute flow is a free vortex, $rc_\theta = \text{constant}$. Therefore, $c_{\theta 1h} = c_{\theta 1t}(r_t/r_h) = 78.6 \times 0.5/0.45 = 87.3$ m/s.

At outlet to the rotor tip,

$$c_{\theta 2t} = c_x \tan \alpha_2 = 136 \times \sqrt{3} = 235.6 \text{ m/s}.$$

Therefore, $c_{\theta 2h} = c_{\theta 2t}(r_t/r_h) = 235.6 \times 0.5/0.45 = 262$ m/s. The flow angles at the hub are

$$\tan \alpha_1 = c_{\theta 1h}/c_x = 87.3/136 = 0.642,$$

$$\tan \beta_1 = U_h/c_x - \tan \alpha_1 = 1.436,$$

$$\tan \alpha_2 = c_{\theta 2h}/c_x = 262/136 = 1.928,$$

$$\tan \beta_2 = U_h/c_x - \tan \alpha_2 = 0.152.$$

Thus, $\alpha_1 = 32.75^\circ$, $\beta_1 = 55.15^\circ$, $\alpha_2 = 62.6^\circ$, $\beta_2 = 8.64^\circ$ at the hub.

- (v) The reaction at the hub can be found by several methods. With eqn. (6.9),

$$R = 1 - k/r^2,$$

and noticing that, from symmetry of the velocity triangles,

$$R = 0.5 \text{ at } r = r_t, \text{ then } k = 0.5r_t^2.$$

Therefore,

$$R_h = 1 - 0.5(0.5/0.45)^2 = 0.382.$$

The velocity triangles will be asymmetric and similar to those in Figure 5.5(b).

The simplicity of the flow under free-vortex conditions is, superficially, very attractive to the designer and many compressors have been designed to conform to this flow. Constant (1945; 1953) may be consulted for an account of early British compressor design methods. Figure 6.4 illustrates the variation of fluid angles and Mach numbers of a typical compressor stage designed for free-vortex flow. Characteristic of this flow are the large fluid deflections near the inner wall and high Mach numbers near the outer wall, both effects being deleterious to efficient performance. A further serious disadvantage is the large amount of rotor twist from root to tip, which adds to the expense of blade manufacture.

**FIGURE 6.4**

Variation of Fluid Angles and Mach Numbers of a Free-Vortex Compressor Stage with Radius (Adapted from Howell, 1945)

Many types of vortex design have been proposed to overcome some of the disadvantages set by free-vortex design and several of these are compared by Horlock (1958). Radial equilibrium solutions for the work and axial velocity distributions of some of these vortex flows in an axial compressor stage follow.

Forced Vortex

This is sometimes called *solid-body* rotation because c_θ varies directly with r . At entry to the rotor assume h_{01} is constant and $c_{\theta 1} = K_1 r$.

With eqn. (6.6b),

$$\frac{d}{dr} = \left(\frac{c_{x1}^2}{2} \right) = -K_1 \frac{d}{dr} (K_1 r^2)$$

and, after integrating,

$$c_{x1}^2 = \text{constant} - 2K_1^2 r^2. \quad (6.10)$$

After the rotor $c_{\theta 2} = K_2 r$ and $h_{02} - h_{01} = U(c_{\theta 2} - c_{\theta 1}) = \Omega(K_2 - K_1)r^2$. Thus, as the work distribution is non-uniform, the radial equilibrium equation in the form eqn. (6.6a) is required for the flow after the rotor:

$$\frac{dh_{02}}{dr} = 2\Omega(K_2 - K_1)r = \frac{d}{dr}\left(\frac{c_{x2}^2}{2}\right) + K_2 \frac{d}{dr}(K_2 r^2).$$

After re-arranging and integrating,

$$c_{x2}^2 = \text{constant} - 2[K_2^2 - \Omega(K_2 - K_1)]r^2. \quad (6.11)$$

The constants of integration in eqns. (6.10) and (6.11) can be found from the continuity of mass flow, i.e.,

$$\frac{\dot{m}}{2\pi\rho} = \int_{r_h}^{r_t} c_{x1} r dr = \int_{r_h}^{r_t} c_{x2} r dr, \quad (6.12)$$

which applies to the assumed incompressible flow.

General Whirl Distribution

The tangential velocity distribution is given by

$$c_{\theta 1} = ar^n - b/r \text{ (before rotor)}, \quad (6.13a)$$

$$c_{\theta 2} = ar^n + b/r \text{ (after rotor)}. \quad (6.13b)$$

The distribution of work for all values of the index n is constant with radius so that, if h_{01} is uniform, h_{02} is also uniform with radius. From eqns. (6.13a and b),

$$\Delta W = h_{02} - h_{01} = U(c_{\theta 2} - c_{\theta 1}) = 2b\Omega. \quad (6.14)$$

Selecting different values of n gives several of the tangential velocity distributions commonly used in compressor design. With $n = 0$, or zero power blading, it leads to the so-called exponential type of stage design (included as an exercise at the end of this chapter). With $n = 1$, or *first power blading*, the stage design is called (incorrectly, as it transpires later) *constant reaction*.

First Power Stage Design

For a given stage temperature rise the discussion in Chapter 5 would suggest the choice of 50% reaction at all radii for the highest stage efficiency. With swirl velocity distributions,

$$c_{\theta 1} = ar - b/r, \quad c_{\theta 2} = ar + b/r \quad (6.15)$$

before and after the rotor, respectively; and rewriting the expression for reaction, eqn. (5.21), as

$$R = 1 - \frac{c_x}{2U}(\tan \alpha_1 + \tan \alpha_2), \quad (6.16)$$

then, using eqn. (6.15),

$$R = 1 - a/\Omega = \text{constant}. \quad (6.17)$$

Implicit in eqn. (6.16) is the assumption that the axial velocity across the rotor remains constant which, of course, is tantamount to ignoring radial equilibrium. The axial velocity *must* change in crossing the rotor row so that eqn. (6.17) is only a crude approximation at the best. Just how crude is this approximation will be indicated later.

Assuming constant stagnation enthalpy at entry to the stage, integrating eqn. (6.6b), the axial velocity distributions before and after the rotor are

$$c_{x1}^2 = \text{constant} - 4a \left(\frac{1}{2} ar^2 - b \ln r \right), \quad (6.18a)$$

$$c_{x2}^2 = \text{constant} - 4a \left(\frac{1}{2} ar^2 + b \ln r \right). \quad (6.18b)$$

More conveniently, these expressions can be written non-dimensionally as

$$\left(\frac{c_{x1}}{U_t} \right)^2 = A_1 - \left(\frac{2a}{\Omega} \right)^2 \left[\frac{1}{2} \left(\frac{r}{r_t} \right)^2 - \frac{b}{ar_t^2} \ln \left(\frac{r}{r_t} \right) \right], \quad (6.19a)$$

$$\left(\frac{c_{x2}}{U_t} \right)^2 = A_2 - \left(\frac{2a}{\Omega} \right)^2 \left[\frac{1}{2} \left(\frac{r}{r_t} \right)^2 + \frac{b}{ar_t^2} \ln \left(\frac{r}{r_t} \right) \right], \quad (6.19b)$$

in which $U_t = \Omega r_t$ is the tip blade speed. The constants A_1, A_2 are not entirely arbitrary as the continuity equation, eqn. (6.12), must be satisfied.

Example 6.2

As an illustration consider a single stage of an axial-flow air compressor of hub–tip ratio 0.4 with a nominally constant reaction (i.e., according to eqn. 6.17) of 50%. Assuming incompressible, inviscid flow, a blade tip speed of 300 m/s, a blade tip diameter of 0.6 m, and a stagnation temperature rise of 16.1°C, determine the radial equilibrium values of axial velocity before and after the rotor. The axial velocity far upstream of the rotor at the casing is 120 m/s. Take C_p for air as 1.005 kJ/(kg°C).

Solution

The constants in eqn. (6.19a) can be easily determined. From eqn. (6.17),

$$2a/\Omega = 2(1 - R) = 1.0.$$

Combining eqns. (6.14) and (6.17),

$$\frac{b}{ar_t^2} = \frac{\Delta W}{2\Omega^2(1 - R)r_t^2} = \frac{C_p \cdot \Delta T_0}{2U_t^2(1 - R)} = \frac{1005 \times 16.1}{300^2} = 0.18.$$

The inlet axial velocity distribution is completely specified and the constant A_1 solved. From eqn. (6.19a),

$$\left(\frac{c_{x1}}{U_t} \right)^2 = A_1 - \left[\frac{1}{2} (r/r_t)^2 - 0.18 \ln (r/r_t) \right].$$

At $r = r_t$, $c_{x1}/U_t = 0.4$ and, hence, $A_1 = 0.66$.

Although an explicit solution for A_2 can be worked out from eqn. (6.19b) and eqn. (6.12), it is far speedier to use a semigraphical procedure. For an arbitrarily selected value of A_2 , the distribution of c_{x2}/U_t is known. Values of $(r/r_t) \times (c_{x2}/U_t)$ and $(r/r_t) \times (c_{x1}/U_t)$ are plotted against r/r_t and the areas under these curves compared. New values of A_2 are then chosen until eqn. (6.12) is satisfied. This procedure is quite rapid and normally requires only two or three attempts to give a satisfactory solution. Figure 6.5 shows the final solution of c_{x2}/U_t obtained after three attempts. The solution is

$$\left(\frac{c_{x2}}{U_t}\right) = 0.56 - \left[\frac{1}{2} \left(\frac{r}{r_t}\right)^2 + 0.18 \ln\left(\frac{r}{r_t}\right) \right].$$

It is illuminating to calculate the actual variation in reaction taking account of the change in axial velocity. From eqn. (5.20) the true reaction across a normal stage is

$$R' = \frac{w_1^2 - w_2^2}{2U(c_{\theta 2} - c_{\theta 1})}.$$

From the velocity triangles, Figure 5.2,

$$w_1^2 - w_2^2 = (w_{\theta 1} + w_{\theta 2})(w_{\theta 1} - w_{\theta 2}) + (c_{x1}^2 - c_{x2}^2).$$

As $w_{\theta 1} + w_{\theta 2} = 2U - (c_{\theta 1} + c_{\theta 2})$ and $w_{\theta 1} - w_{\theta 2} = c_{\theta 2} - c_{\theta 1}$,

$$R' = 1 - \frac{c_{\theta 1} + c_{\theta 2}}{2U} + \frac{c_{x1}^2 - c_{x2}^2}{2U(c_{\theta 2} - c_{\theta 1})}.$$

FIGURE 6.5

Solution of Exit Axial-Velocity Profile for a First Power Stage

For the first power swirl distribution, eqn. (6.15),

$$R' = 1 - \frac{a}{\Omega} + \frac{c_{x1}^2 - c_{x2}^2}{4\Omega b}.$$

From the radial equilibrium solution in eqns. (6.19a and b), after some rearrangement,

$$\frac{c_{x1}^2 - c_{x2}^2}{4\Omega b} = \frac{A_1 - A_2}{2\psi_t} + \left(\frac{2a}{\Omega}\right) \ln\left(\frac{r}{r_t}\right),$$

where

$$\psi_t = \frac{\Delta W}{U_t^2} = \frac{C_p \Delta T_0}{\Omega^2 r_t^2}.$$

In this example, $1 - a/\Omega = \frac{1}{2}$, $\psi_t = 0.18$,

$$R' = 0.778 + \ln(r/r_t).$$

The true reaction variation is shown in Figure 6.5 and it is evident that eqn. (6.17) is *invalid* as a result of the axial velocity changes. ■

6.4 THE DIRECT PROBLEM

The flow angle variation is specified in the direct problem and the radial equilibrium equation enables the solution of c_x and c_θ to be found. The general radial equilibrium equation can be written in the form

$$\frac{dh_0}{dr} - T \frac{ds}{dr} = \frac{c_\theta^2}{r} + c \frac{dc}{dr} = \frac{c^2 \sin^2 \alpha}{r} + c \frac{dc}{dr}, \quad (6.20)$$

as $c_\theta = c \sin \alpha$.

If both dh_0/dr and ds/dr are zero, eqn. (6.20) integrated gives

$$\log c = -\int \sin^2 \alpha \frac{dr}{r} + \text{constant}$$

or, if $c = c_m$ at $r = r_m$, then

$$\frac{c}{c_m} = \exp\left(-\int_{r_m}^r \sin^2 \alpha \frac{dr}{r}\right). \quad (6.21)$$

If the flow angle α is held constant, eqn. (6.21) simplifies still further:

$$\frac{c}{c_m} = \frac{c_x}{c_{xm}} = \frac{c_\theta}{c_{\theta m}} = \left(\frac{r}{r_m}\right)^{-\sin^2 \alpha}. \quad (6.22)$$

The vortex distribution represented by eqn. (6.22) is frequently employed in practice as untwisted blades are relatively simple to manufacture.

The general solution of eqn. (6.20) can be found by introducing a suitable *integrating factor* into the equation. Multiplying throughout by $\exp\left[2\int \sin^2\alpha dr/r\right]$ it follows that

$$\frac{d}{dr}\left\{c^2\exp\left[2\int \sin^2\alpha dr/r\right]\right\} = 2\left(\frac{dh_0}{dr} - T\frac{ds}{dr}\right)\exp\left[2\int \sin^2\alpha dr/r\right].$$

After integrating and inserting the limit $c = c_m$ at $r = r_m$,

$$c^2\exp\left[2\int^r \sin^2\alpha dr/r\right] - c_m^2\exp\left[2\int^{r_m} \sin^2\alpha dr/r\right] = 2\int_{r_m}^r \left(\frac{dh_0}{dr} - T\frac{ds}{dr}\right)\exp\left[2\int \sin^2\alpha dr/r\right] dr. \quad (6.23a)$$

Particular solutions of eqn. (6.23a) can be readily obtained for simple radial distributions of α , h_0 , and s . Two solutions are considered here in which both $2dh_0/dr = kc_m^2/r_m$ and $ds/dr = 0$, k being an arbitrary constant.

(i) Let $a = 2\sin^2\alpha$. Then $\exp\left[2\int \sin^2\alpha dr/r\right] = r^a$ and, hence,

$$\left(\frac{c}{c_m}\right)^2 \left(\frac{r}{r_m}\right)^a = 1 + \frac{k}{1+a} \left[\left(\frac{r}{r_m}\right)^{1+a} - 1\right]. \quad (6.23b)$$

Equation (6.22) is obtained immediately from this result with $k = 0$.

(ii) Let $br/r_m = 2\sin^2\alpha$. Then,

$$c^2\exp(br/r_m) - c_m^2\exp(b) = (kc_m^2/r_m) \int_{r_m}^r \exp(br/r_m) dr$$

and eventually,

$$\left(\frac{c}{c_m}\right)^2 = \frac{k}{b} + \left(1 - \frac{k}{b}\right)\exp\left[b\left(1 - \frac{r}{r_m}\right)\right]. \quad (6.23c)$$

6.5 COMPRESSIBLE FLOW THROUGH A FIXED BLADE ROW

In the blade rows of high performance gas turbines, fluid velocities approaching, or even exceeding, the speed of sound are common and compressibility effects may no longer be ignored. A simple analysis is outlined here for the inviscid flow of a perfect gas through a *fixed* row of blades which, nevertheless, can be extended to the flow through moving blade rows.

The radial equilibrium equation, eqn. (6.6a), applies to *compressible* flow as well as incompressible flow. With constant stagnation enthalpy and constant entropy, a free-vortex flow therefore implies uniform axial velocity downstream of a blade row, regardless of any *density* changes incurred in passing through the blade row. In fact, for high-speed flows there *must* be a density change in the blade row, which implies a streamline shift as shown in Figure 6.1. This may be illustrated by considering the free-vortex flow of a perfect gas as follows. In radial equilibrium,

$$\frac{1}{\rho} \frac{dp}{dr} = \frac{c_\theta^2}{r} = \frac{K^2}{r^3} \quad \text{with } c_\theta = K/r.$$

For reversible adiabatic flow of a perfect gas, $\rho = Ep^{1/\gamma}$, where E is constant. Thus,

$$\int p^{-1/\gamma} dp = EK^2 \int r^{-3} dr + \text{constant},$$

therefore,

$$p = \left[\text{constant} = \left(\frac{\gamma-1}{2\gamma} \right) \frac{EK^{2\gamma}}{r^2} \right]^{\gamma/(\gamma-1)}. \quad (6.24)$$

For this free-vortex flow the pressure, and therefore the density also, must be larger at the casing than at the hub. The density difference from hub to tip may be appreciable in a high velocity, high swirl angle flow. If the fluid is without swirl at entry to the blades the density will be uniform. Therefore, from continuity of mass flow there must be a redistribution of fluid in its passage across the blade row to compensate for the changes in density. Thus, for this blade row, the continuity equation is

$$\dot{m} = \rho_1 A_1 c_{x1} = 2\pi c_{x2} \int_{r_h}^{r_t} \rho_2 r dr, \quad (6.25)$$

where ρ_2 is the density of the swirling flow, obtainable from eqn. (6.24).

6.6 CONSTANT SPECIFIC MASS FLOW

Although there appears to be no evidence that the redistribution of the flow across blade rows is a source of inefficiency, it has been suggested by Horlock (1966) that the radial distribution of c_θ for each blade row is chosen so that the product of axial velocity and density is constant with radius, i.e.,

$$d\dot{m}/dA = \rho c_x = \rho c \cos \alpha = \rho_m c_m \cos \alpha_m = \text{constant}, \quad (6.26)$$

where subscript m denotes conditions at $r = r_m$. This *constant specific mass flow design* is the logical choice when radial equilibrium theory is applied to compressible flows as the assumption that $c_r = 0$ is then likely to be realised.

Solutions may be determined by means of a simple numerical procedure and, as an illustration of one method, a turbine stage is considered here. It is convenient to assume that the stagnation enthalpy is uniform at nozzle entry, the entropy is constant throughout the stage, and the fluid is a perfect gas. At nozzle exit under these conditions the equation of radial equilibrium, eqn. (6.20), can be written as

$$dc/c = -\sin^2 \alpha dr/r. \quad (6.27)$$

From eqn. (6.1), noting that at constant entropy the acoustic velocity $a = \sqrt{dp/d\rho}$,

$$\frac{1}{\rho} \frac{d\rho}{dr} = \frac{1}{\rho} \left(\frac{d\rho}{dp} \right) \left(\frac{dp}{dr} \right) = \frac{a^2}{\rho} \frac{d\rho}{dr} = \frac{c^2}{r} \sin^2 \alpha,$$

therefore,

$$d\rho/\rho = M^2 \sin^2 \alpha dr/r, \quad (6.28a)$$

where the flow Mach number

$$M = c/a = c/\sqrt{\gamma RT}. \quad (6.28b)$$

The isentropic relation between temperature and density for a perfect gas is

$$T/T_m = (\rho/\rho_m)^{\gamma-1},$$

which after logarithmic differentiation gives

$$dT/T = (\gamma - 1)d\rho/\rho. \quad (6.29)$$

Using this set of equations the procedure for determining the nozzle exit flow is as follows. Starting at $r = r_m$, values of c_m , α_m , T_m , and ρ_m are assumed to be known. For a small finite interval Δr , the changes in velocity Δc , density $\Delta \rho$, and temperature ΔT can be computed using eqns. (6.27), (6.28), and (6.29), respectively. Hence, at the new radius $r = r_m + \Delta r$, the velocity $c = c_m + \Delta c$, the density $\rho = \rho_m + \Delta \rho$ and temperature $T = T_m + \Delta T$ are obtained. The corresponding flow angle α and Mach number M can now be determined from eqns. (6.26) and (6.28b), respectively. Thus, all parameters of the problem are known at radius $r = r_m + \Delta r$. This procedure is repeated for further increments in radius to the casing and again from the mean radius to the hub.

Figure 6.6 shows the distributions of flow angle and Mach number computed with this procedure for a turbine nozzle blade row of 0.6 hub–tip radius ratio. The input data used was $\alpha_m = 70.4^\circ$ and $M = 0.907$ at the mean radius. Air was assumed at a stagnation pressure of 859 kPa and a stagnation temperature of 465°K. A remarkable feature of these results is the almost uniform swirl angle that is obtained.

With the nozzle exit flow fully determined the flow at rotor outlet can now be computed by a similar procedure. The procedure is a little more complicated than that for the nozzle row because the specific work done by the rotor is not uniform with radius. Across the rotor, using the notation of Chapter 4,

$$h_{03} - h_{03} = U(c_{\theta 2} + c_{\theta 3}), \quad (6.30a)$$

FIGURE 6.6

Flow Angle and Mach Number Distributions with Radius of a Nozzle Blade Row Designed for Constant Specific Mass Flow

and, hence, the gradient in stagnation enthalpy after the rotor is

$$dh_{03}/dr = -d[U(c_{\theta 2} - c_{\theta 3})]/dr = -d(Uc_{\theta 2})/dr - d(Uc_3 \sin \alpha_3)/dr.$$

After differentiating the last term,

$$-dh_0 = d(Uc_{\theta 2}) + U(c \sin \alpha dr/r + \sin \alpha dc + c \cos \alpha d\alpha), \quad (6.30b)$$

the subscript 3 having now been dropped.

From eqn. (6.20) the radial equilibrium equation applied to the rotor exit flow is

$$dh_0 = c^2 \sin^2 \alpha dr/r + c dc. \quad (6.30c)$$

After logarithmic differentiation of $\rho c \cos \alpha = \text{constant}$,

$$d\rho/\rho + dc/c = \tan \alpha d\alpha. \quad (6.31)$$

Eliminating successively dh_0 between eqns. (6.30b) and (6.30c), $d\rho/\rho$ between eqns. (6.28) and (6.31), and finally $d\alpha$ from the resulting equations gives

$$\frac{dc}{c} \left(1 + \frac{c_{\theta}}{U}\right) = -\sin^2 \alpha \left[\frac{d(rc_{\theta})}{rc_{\theta}} + \left(1 + \frac{c_{\theta}}{U} + M_x^2\right) \frac{dr}{r} \right], \quad (6.32)$$

where $M_x = M \cos \alpha = c \cos \alpha / \sqrt{\gamma RT}$ and the static temperature

$$T = T_3 = T_{03} - c_3^2 / (2C_p) = T_{02} - \left[U(c_{\theta 2} + c_{\theta 3}) + \frac{1}{2} c_3^2 \right] / C_p. \quad (6.33)$$

The verification of eqn. (6.32) is left as an exercise for the diligent student.

Provided that the exit flow angle α_3 at $r = r_m$ and the mean rotor blade speeds are specified, the velocity distribution, etc., at rotor exit can be readily computed from these equations.

6.7 OFF-DESIGN PERFORMANCE OF A STAGE

A turbine stage is considered here although, with some minor modifications, the analysis can be made applicable to a compressor stage.

Assuming the flow is at constant entropy, apply the radial equilibrium equation, eqn. (6.6a), to the flow on both sides of the rotor:

$$\frac{dh_{03}}{dr} = \frac{dh_{02}}{dr} - \Omega \frac{d}{dr}(rc_{\theta 2} + rc_{\theta 3}) = c_{x3} \frac{dc_{x3}}{dr} + \frac{c_{\theta 3}}{r} \frac{d}{dr}(rc_{\theta 3}).$$

Therefore,

$$c_{x2} \frac{dc_{x2}}{dr} + \left(\frac{c_{\theta 2}}{r} - \Omega \right) \frac{d}{dr}(rc_{\theta 2}) = c_{x3} \frac{dc_{x3}}{dr} + \left(\frac{c_{\theta 3}}{r} + \Omega \right) \frac{d}{dr}(rc_{\theta 3}).$$

Substituting $c_{\theta 3} = c_{x3} \tan \beta_3 - \Omega r$ into this equation, after some simplification,

$$c_{x2} \frac{dc_{x2}}{dr} + \left(\frac{c_{\theta 2}}{r} - \Omega \right) \frac{d}{dr}(rc_{\theta 2}) = c_{x3} \frac{dc_{x3}}{dr} + \frac{c_{x3}}{r} \tan \beta_3 \frac{d}{dr}(rc_{x3} \tan \beta_3) - 2\Omega c_{x3} \tan \beta_3. \quad (6.34)$$

In a particular problem the quantities c_{x2} , $c_{\theta2}$, β_3 are known functions of radius and Ω can be specified. Equation (6.34) is thus a first-order differential equation in which c_{x3} is unknown and may best be solved, in the general case, by numerical iteration. This procedure requires a guessed value of c_{x3} at the hub and, by applying eqn. (6.34) to a small interval of radius Δr , a new value of c_{x3} at radius $r_h + \Delta r$ is found. By repeating this calculation for successive increments of radius a complete velocity profile c_{x3} can be determined. Using the continuity relation

$$\int_{r_h}^{r_t} c_{x3} r dr = \int_{r_h}^{r_t} c_{x2} r dr,$$

this initial velocity distribution can be integrated and a new, more accurate, estimate of c_{x3} at the hub then found. Using this value of c_{x3} the step-by-step procedure is repeated as described and again checked by continuity. This iterative process is normally rapidly convergent and, in most cases, three cycles of the calculation enable a sufficiently accurate exit velocity profile to be found.

The off-design performance may be obtained by making the approximation that the rotor relative exit angle β_3 and the nozzle exit angle α_2 remain constant at a particular radius with a change in mass flow. This approximation is not unrealistic as cascade data (see Chapter 3) suggest that fluid angles at outlet from a blade row alter very little with change in incidence up to the stall point.

Although any type of flow through a stage may be successfully treated using this method, rather more elegant solutions in closed form can be obtained for a few special cases. One such case is outlined next for a free-vortex turbine stage whilst other cases are already covered by eqns. (6.21)–(6.23).

6.8 FREE-VORTEX TURBINE STAGE

Suppose, for simplicity, a free-vortex stage is considered where, at the design point, the flow at rotor exit is completely axial (i.e., without swirl). At stage entry the flow is again supposed completely axial and of constant stagnation enthalpy h_{01} . Free-vortex conditions prevail at entry to the rotor, $rc_{\theta2} = rc_{x2} \tan \alpha_2 = \text{constant}$. The problem is to find how the axial velocity distribution at rotor exit varies as the mass flow is altered away from the design value.

At off-design conditions the relative rotor exit angle β_3 is assumed to remain equal to the value β_3^* at the design mass flow (* denotes design conditions). Thus, referring to the velocity triangles in Figure 6.7, at off-design conditions the swirl velocity $c_{\theta3}$ is evidently non-zero:

$$c_{\theta3} = c_{x3} \tan \beta_3 - U = c_{x3} \tan \beta_3^* - \Omega r. \quad (6.35)$$

At the design condition $c_{\theta3}^* = 0$ and so

$$c_{x3}^* \tan \beta_3^* = \Omega r. \quad (6.36)$$

Combining eqns. (6.35) and (6.36),

$$c_{\theta3} = \Omega r \left(\frac{c_{x3}}{c_{x3}^*} - 1 \right). \quad (6.37)$$

The radial equilibrium equation at rotor outlet gives

$$\frac{dh_{03}}{dr} = c_{x3} \frac{dc_{x3}}{dr} + \frac{c_{\theta3}}{r} \frac{d}{dr} (rc_{\theta3}) = -\Omega \frac{d}{dr} (rc_{\theta3}), \quad (6.38)$$

**FIGURE 6.7**

Design and Off-Design Velocity Triangles for a Free-Vortex Turbine Stage

after combining with eqn. (6.33), noting that $dh_{02}/dr = 0$ and that $(d/dr)(rc_{\theta 2}) = 0$ at all mass flows. From eqn. (6.37),

$$\Omega + \frac{c_{\theta 3}}{r} = \Omega \frac{c_{x3}}{c_{x3}^*}, \quad rc_{\theta 3} = \Omega r^2 \left(\frac{c_{x3}}{c_{x3}^*} - 1 \right),$$

which when substituted into eqn. (6.38) gives

$$-\frac{dc_{x3}}{dr} = \frac{\Omega^2}{c_{x3}^*} \left[2r \left(\frac{c_{x3}}{c_{x3}^*} - 1 \right) + \frac{r^2}{c_{x3}^*} \frac{dc_{x3}}{dr} \right].$$

After rearranging,

$$\frac{dc_{x3}}{c_{x3} - c_{x3}^*} = \frac{-d(\Omega^2 r^2)}{(c_{x3}^{*2} + \Omega^2 r^2)}. \quad (6.39)$$

Equation (6.39) is immediately integrated in the form

$$\frac{c_{x3} - c_{x3}^*}{c_{x3m} - c_{x3}^*} = \frac{c_{x3}^{*2} + \Omega^2 r_m^2}{c_{x3}^{*2} + \Omega^2 r^2}, \quad (6.40a)$$

**FIGURE 6.8**

Off-Design Rotor Exit Flow Coefficients

where $c_{x3} = c_{x3m}$ at $r = r_m$. Equation (6.40a) is more conveniently expressed in a non-dimensional form by introducing flow coefficients $\phi = c_{x3}/U_m$, $\phi^* = c_{x3}^*/U_m$, and $\phi_m = c_{x3m}/U_m$. Thus,

$$\frac{\phi/\phi^* - 1}{\phi_m/\phi^* - 1} = \frac{\phi^{*2} + 1}{\phi^{*2} + (r/r_m)^2}, \quad (6.40b)$$

If r_m is the mean radius then $c_{x3m} \cong c_{x1}$ and, therefore, ϕ_m provides an approximate measure of the overall flow coefficient for the machine (Note: c_{x1} is uniform).

The results of this analysis are shown in Figure 6.8 for a representative design flow coefficient $\phi^* = 0.8$ at several different off-design flow coefficients ϕ_m , with $r/r_m = 0.8$ at the hub and $r/r_m = 1.2$ at the tip. It is apparent for values of $\phi_m < \phi^*$, that c_{x3} increases from hub to tip; conversely for $\phi_m > \phi^*$, c_{x3} decreases towards the tip.

The foregoing analysis is only a special case of the more general analysis of free-vortex turbine and compressor flows (Horlock and Dixon, 1966) in which rotor exit swirl, $rc_{\theta 3}^*$ is constant (at design conditions) is included. However, from Horlock and Dixon, it is quite clear that even for fairly large values of α_{3m}^* , the value of ϕ is little different from the value found when $\alpha_3^* = 0$, all other factors being equal. In Figure 6.8 values of ϕ are shown when $\alpha_{3m}^* = 31.4^\circ$ at $\phi_m = 0.4$ ($\phi^* = 0.8$) for comparison with the results obtained when $\alpha_3^* = 0$.

It should be noted that the rotor efflux flow at off-design conditions is *not* a free vortex.

6.9 ACTUATOR DISC APPROACH

In the radial equilibrium design method it was assumed that all radial motion took place within the blade row. However, in most turbomachines of low hub-tip ratio, appreciable radial velocities can

be measured outside of the blade row. Figure 6.9, taken from a review paper by Hawthorne and Horlock (1962), shows the distribution of the axial velocity component at various axial distances upstream and downstream of an isolated row of stationary inlet guide vanes. This figure clearly illustrates the appreciable redistribution of flow in regions outside of the blade row and that radial velocities must exist in these regions. For the flow through a single row of rotor blades, the variation in pressure (near the hub and tip) and variation in axial velocity (near the hub), both as functions of axial position, are shown in Figure 6.10, also taken from Hawthorne and Horlock. Clearly, radial equilibrium is not established entirely within the blade row.

A more accurate form of three-dimensional flow analysis than radial equilibrium theory is obtained with the *actuator disc* concept. The idea of an actuator disc is quite old and appears to have been first used in the theory of propellers; it has since evolved into a fairly sophisticated method of analysing flow problems in turbomachinery. To appreciate the idea of an actuator disc, imagine that the axial width of each blade row is shrunk while, at the same time, the space-chord ratio, the blade angles, and overall length of machine are maintained constant. As the deflection through each blade row

FIGURE 6.9

Variation of the Distribution in Axial Velocity through a Row of Guide Vanes (Adapted from Hawthorne and Horlock, 1962)

**FIGURE 6.10**

(a) Pressure Variation in the Neighbourhood of a Rotating Blade Row; (b) Axial Velocity at the Hub in the Neighbourhood of a Rotating Blade Row (Adapted from Hawthorne and Horlock, 1962)

for a given incidence is, apart from Reynolds number and Mach number effects (cf. Chapter 3 on cascades), fixed by the cascade geometry, a blade row of reduced width may be considered to affect the flow in exactly the same way as the original row. In the limit as the axial width vanishes, the blade row becomes, conceptually, a *plane discontinuity* of tangential velocity—the actuator disc. Note that while the tangential velocity undergoes an abrupt change in direction, the axial and radial velocities are continuous across the disc.

An isolated actuator disc is depicted in Figure 6.11 with radial equilibrium established at fairly large axial distances from the disc. An approximate solution to the velocity fields upstream and downstream of the actuator can be found in terms of the axial velocity distributions *far upstream* and *far downstream* of the disc. The detailed analysis exceeds the scope of this book, involving the solution of the equations of motion, the equation of continuity, and the satisfaction of boundary conditions at the walls and disc. The form of the approximate solution is of considerable interest and is quoted here.

For convenience, conditions far upstream and far downstream of the disc are denoted by subscripts $\infty 1$ and $\infty 2$, respectively (Figure 6.11). Actuator disc theory proves that at the disc ($x = 0$), at any given radius, the axial velocity is equal to the *mean* of the axial velocities at $\infty 1$ and $\infty 2$ at the *same* radius, or

$$c_{x01} = c_{x02} = \frac{1}{2}(c_{x\infty 1} + c_{x\infty 2}). \quad (6.41)$$

Subscripts 01 and 02 denote positions immediately upstream and downstream, respectively, of the actuator disc. Equation (6.41) is known as the *mean-value rule*.

In the downstream flow field ($x \geq 0$), the *difference* in axial velocity at some position (x, r_A) to that at position ($x = \infty, r_A$) is conceived as a velocity perturbation. Referring to Figure 6.12, the axial velocity perturbation at the disc ($x = 0, r_A$) is denoted by Δ_0 and at position (x, r_A) by Δ . The important result of actuator disc theory is that velocity perturbations *decay exponentially* away from the disc. This is also true for the upstream flow field ($x \leq 0$). The result obtained for the decay rate is

$$\Delta/\Delta_0 = 1 - \exp[\mp \pi x / (r_t - r_h)], \quad (6.42)$$

FIGURE 6.11

The Actuator Disc Assumption (After Horlock, 1958)

**FIGURE 6.12**

Variation in Axial Velocity with Axial Distance from the Actuator Disc

where the minus and plus signs apply to the flow regions $x \geq 0$ and $x \leq 0$, respectively. Equation (6.42) is often called the *settling-rate rule*. Since $c_{x1} = c_{x\infty 1} + \Delta$, $c_{x2} = c_{x\infty 2} - \Delta$ and noting that $\Delta_0 = \frac{1}{2}(c_{x\infty 1} - c_{x\infty 2})$, eqns. (6.41) and (6.42) combine to give

$$c_{x1} = c_{x\infty 1} - \frac{1}{2}(c_{x\infty 1} - c_{x\infty 2})\exp[\pi x/(r_t - r_h)], \quad (6.43a)$$

$$c_{x2} = c_{x\infty 2} + \frac{1}{2}(c_{x\infty 1} - c_{x\infty 2})\exp[-\pi x/(r_t - r_h)]. \quad (6.43b)$$

At the disc, $x = 0$, eqns. (6.43a and b) reduce to eqn. (6.41). It is of particular interest to note, in Figures 6.9 and 6.10, how closely isolated actuator disc theory compares with experimentally derived results.

Blade Row Interaction Effects

The spacing between consecutive blade rows in axial turbomachines is usually sufficiently small for mutual flow interactions to occur between the rows. This interference may be calculated by an extension of the results obtained from isolated actuator disc theory. As an illustration, the simplest case of two actuator discs situated a distance δ apart from one another is considered. The extension to the case of a large number of discs is given in Hawthorne and Horlock (1962).

Consider each disc in turn as though it were in isolation. Referring to Figure 6.13, disc A, located at $x = 0$, changes the far upstream velocity $c_{x\infty 1}$ to $c_{x\infty 2}$ far downstream. Let us suppose for simplicity that the effect of disc B, located at $x = \delta$, exactly cancels the effect of disc A (i.e., the velocity far upstream of disc B is $c_{x\infty 2}$, which changes to $c_{x\infty 1}$ far downstream). Thus, for disc A in isolation,

$$c_x = c_{x\infty 1} - \frac{1}{2}(c_{x\infty 1} - c_{x\infty 2})\exp\left[\frac{-\pi|x|}{H}\right], \quad x \leq 0, \quad (6.44)$$

$$c_x = c_{x\infty 2} + \frac{1}{2}(c_{x\infty 1} - c_{x\infty 2})\exp\left[\frac{-\pi|x|}{H}\right], \quad x \geq 0, \quad (6.45)$$

**FIGURE 6.13**

Interaction between Two Closely Spaced Actuator Discs

where $|x|$ denotes modulus of x and $H = r_t - r_h$.

For disc B in isolation,

$$c_x = c_{x \rightarrow 2} - \frac{1}{2}(c_{x \rightarrow 2} - c_{x \rightarrow 1}) \exp \left[\frac{-\pi|x - \delta|}{H} \right], \quad x \leq \delta, \quad (6.46)$$

$$c_x = c_{x \rightarrow 1} + \frac{1}{2}(c_{x \rightarrow 2} - c_{x \rightarrow 1}) \exp \left[\frac{-\pi|x - \delta|}{H} \right], \quad x \geq \delta. \quad (6.47)$$

Now the combined effect of the two discs is most easily obtained by extracting from the preceding four equations the velocity perturbations appropriate to a given region and adding these to the related radial equilibrium velocity for $x \leq 0$, and to $c_{x \rightarrow 1}$ the perturbation velocities from eqns. (6.44) and (6.46):

$$c_x = c_{x \rightarrow 1} - \frac{1}{2}(c_{x \rightarrow 1} - c_{x \rightarrow 2}) \left\{ \exp \left[\frac{-\pi|x|}{H} \right] - \exp \left[\frac{-\pi|x - \delta|}{H} \right] \right\}. \quad (6.48)$$

For the region $0 \leq x \leq \delta$,

$$c_x = c_{x \rightarrow 2} + \frac{1}{2}(c_{x \rightarrow 1} - c_{x \rightarrow 2}) \left\{ \exp \left[\frac{-\pi|x|}{H} \right] + \exp \left[\frac{-\pi|x - \delta|}{H} \right] \right\}. \quad (6.49)$$

For the region $x \geq \delta$,

$$c_x = c_{x \rightarrow 1} + \frac{1}{2}(c_{x \rightarrow 1} - c_{x \rightarrow 2}) \left\{ \exp \left[\frac{-\pi|x|}{H} \right] - \exp \left[\frac{-\pi|x - \delta|}{H} \right] \right\}. \quad (6.50)$$

Figure 6.13 indicates the variation of axial velocity when the two discs are regarded as *isolated* and when they are *combined*. It can be seen from these equations that, as the gap between these two discs is increased, so the perturbations tend to vanish. Thus, in turbomachines where δ/r is fairly small (e.g., the front stages of aircraft axial compressors or the rear stages of condensing steam turbines), interference effects are strong and then the simpler radial equilibrium analysis is inadequate.

Application to Compressible Flow

An elegant analysis to the problem of compressible flow through a multi-stage turbomachine has been developed by Lewis (1995) using an innovative application of actuator disc theory, which models the influence of density gradients on the meridional flow through the turbomachine. The analysis takes advantage of previous solutions for the flow induced by source discs and the analogy between compressible flows and incompressible flows with source distributions. The following conclusions were drawn by Lewis:

- (i) Vortex actuator disc theory can be extended to include compressibility effects, which may be superimposed linearly upon rotational effects. The influence of density gradients upon the meridional flow is considerable for typical free-vortex axial turbine stages.
- (ii) Plane actuator discs can be easily replaced by *smeared actuator discs* distributed uniformly between the leading and trailing edge planes of each blade row.
- (iii) A simple analysis extending cylindrical compressible actuator disc theory to axial turbines with flared annuli has been completed for application to multi-stage turbines.
- (iv) The method is ideal for rapid computational analysis.

Figure 6.14 illustrates the predicted axial velocity distribution at the hub and tip radii of a model turbine stage (Table 6.1 gives the main details) resulting from axially smeared actuator discs to represent the blade rows. This smearing spreads the density gradient fairly realistically between the blade leading and trailing edges. The rather large change in axial velocity observed is the result of the overall decrease in density—the stage chosen was cylindrical. Usual design practice would be to increase the annular area to maintain a more or less constant value of axial velocity.

6.10 COMPUTER-AIDED METHODS OF SOLVING THE THROUGH-FLOW PROBLEM

Actuator disc theory has given an improved understanding of the complicated meridional through-flow problem in turbomachines of simple geometry and flow conditions, but its application to the design of axial-flow compressors and turbines is still limited. Advanced computational methods are still being evolved for predicting the meridional *compressible flow* in turbomachines with flared annuli, some of which are now described

Through-Flow Methods

In any of the so-called through-flow methods the equations of motion to be solved are simplified. Firstly, the flow is taken to be steady in both the absolute and relative frames of reference. Secondly, outside of the blade rows the flow is assumed to be axisymmetric, which means that the effects of

FIGURE 6.14

Flow through Turbine Stage in Cylindrical Annulus with Smeared Actuator Disc Representation of the Blade Rows (Adapted from Lewis 1995 with the permission of Elsevier Science Ltd.)

Table 6.1 Specification of Model Turbine Stage

Hub/tip ratio, r_h/r_t	0.6
Flow coefficient at r.m.s. radius	0.5
Work coefficient at r.m.s. radius	1.0
Exit mach number M_{2h} at root radius	1.0
Total-to-total efficiency	92 %
Zero swirl flow upstream of stator	
Free-vortex flow downstream of stator	
Perfect gas (air) assumed	

wakes from an upstream blade row are understood to have “mixed out” so as to give uniform circumferential conditions. Within the blade rows the effects of the blades themselves are modelled by using a passage averaging technique or an equivalent process. Clearly, with these major assumptions, solutions obtained with these through-flow methods can be only approximations to the real flow. As a step beyond this Stow (1985) outlined the ways, supported by equations, of including the viscous flow effects into the flow calculations.

Three of the most widely used techniques for solving through-flow problems are

- (i) Streamline curvature, which is based on an iterative procedure, is described in some detail by Macchi (1985) and earlier by Smith (1966). It is the oldest and most widely used method for

solving the through-flow problem in axial-flow turbomachines and has the intrinsic capability of being able to handle variously shaped boundaries with ease. The method is widely used in the gas turbine industry.

- (ii) Matrix through-flow or finite difference solutions (Marsh, 1968), in which computations of the radial equilibrium flow field are made at a number of axial locations *within* each blade row as well as at the leading and trailing edges and outside of the blade row. An illustration of a typical computing mesh for a single blade row taken from Macchi (1985) is shown in Figure 6.15.
- (iii) Time-marching (Denton, 1985), in which the computation starts from some assumed flow field and the governing equations are marched forward with time. The method requires a large number of iterations needed to reach a convergent solution but can be used to solve both subsonic and supersonic flow. For highly loaded blade rows, which can include patches of supersonic flow, this approach is the most suitable.

All three methods solve the same equations of fluid motion, energy, and state for an axisymmetric flow through a turbomachine with varying hub and tip radii and, therefore, lead to the same solution. According to Denton and Dawes (1999) the streamline curvature method remains the dominant numerical scheme amongst these through-flow methods because of its simplicity and ability to cope with mixed subsonic and supersonic flows. The only alternative method commonly used is the stream function method. In effect the same equations are solved as the streamline curvature method except that an axisymmetric stream function is employed as the primary variable. This method does have the advantage of simplifying the numerics by satisfying the continuity equation via the boundary conditions of the stream function at the hub and casing. However, this method fails when the flow becomes transonic because then there are two possible velocity distributions and it is not obvious whether to take the subsonic or the supersonic solution.

FIGURE 6.15

Typical Computational Mesh for a Single Blade Row (Adapted from Macchi, 1985)

6.11 APPLICATION OF COMPUTATIONAL FLUID DYNAMICS TO THE DESIGN OF AXIAL TURBOMACHINES

Up to about 1990 the aerodynamic design of most axial turbomachines was executed by the so-called through-flow methods. The use of these models depended upon a long and slow process of iteration. The way this worked was to *design and build* a machine from the existing database. Then, from tests done on the fabricated hardware, the existing flow correlations would be updated and applied to obtain a new axisymmetric design of the configuration. Although this approach did often produce excellent machines with outstanding aerodynamic performance, the demand for more rapid methods at less cost forced a major reappraisal of the methodology used. The foundation of this new methodology required aerodynamic models with a resolution greater than the previously used axisymmetric flow models. As well as this it was essential that the models used could complete the task in a matter of hours rather than weeks.

Over the last two decades numerous papers have reviewed the state of art and developments of computational fluid dynamics (CFD) as applied to turbomachinery design and flow prediction. Only a few are considered here, and then only very briefly. Adamczyk (2000) presented a particularly impressive and valuable paper summarising the state of three-dimensional CFD-based models of the time-averaged flow within axial flow multi-stage turbomachines. His paper placed emphasis on models that are compatible with the industrial design environment and would offer the potential of providing credible results at both design and off-design operating conditions. Adamczyk laid stress on the need to develop models *free of aerodynamic input from semi-empirical design data*. He developed a model referred to as *the average-passage flow model*, which described the time-averaged flow field within a typical blade passage of a blade row embedded within a multi-stage configuration. The resulting flow field is periodic over the pitch of the blade row of interest.* With this model the geometry is the input and the output is the flow field generated by the geometry. During the design process, geometry updates are derived exclusively from results obtained with the average-passage model. The credibility of an average-passage flow simulation is not tied to aerodynamic matching information provided by a through-flow system or data match. The credibility is, in fact, linked to the models used to account for the effects of the unsteady flow environment on the average-passage flow field. The effect of the *unsteady deterministic* flow field on aerodynamic matching of stages is accounted for by velocity correlations within the momentum equations.**

According to Horlock and Denton (2003) modern turbomachinery design relies almost completely on CFD to develop three-dimensional blade sections. Simple methods of determining performance with empirical input, such as described in this book, are still needed for the mean radius design and for through-flow calculations. It is often emphasised by experienced designers that, if the one-dimensional preliminary design is incorrect, e.g., the blade diffusion factors and stage loading, then no amount of CFD will produce a good design! What CFD does provide is the ability to exploit the

*In Chapter 1 of this book it was observed that turbomachines can work the way they do, i.e., imparting or extracting energy, only because of the *unsteady flow effects* taking place within the machine. This flow unsteadiness relates primarily to the blade passage spacing and rotational speed of the rotor and not to small-scale turbulence.

**The term *unsteady deterministic* refers to all time-dependent behaviour linked to shaft rotational speed. All unsteady behaviour not linked to shaft rotational speed is referred to as *non-deterministic*.

three-dimensional nature of the flow to suppress deleterious features such as corner stall in compressors or strong secondary flows in turbines.

Horlock and Denton (2003) indicated that loss predictions by CFD are still not accurate and that interpretation of the computations requires considerable skill and experience. Good physical understanding and judgement of when the flow has been improved remain very important. There are many reported examples of the successful use of CFD to improve designs but, it is suspected, many unreported failures. Examples of success are the use of bowed blades to control secondary loss in turbines and the use of sweep and bow to control or reduce corner separations in compressors. Both of these techniques are now routinely employed in production machines.

The outlook for CFD is that its capabilities are continuously developing and that future turbomachinery will continue to be more dependent on it than at present. The trend, as outlined by Adamczyk (2000), is towards multi-stage and unsteady flow computations with more detailed geometrical features and larger computational meshes.

6.12 SECONDARY FLOWS

No account of three-dimensional motion in axial turbomachines would be complete without giving, at least, a brief description of secondary flow. When a fluid particle possessing *rotation* is turned (e.g., by a cascade) its axis of rotation is deflected in a manner analogous to the motion of a gyroscope, i.e., in a direction perpendicular to the direction of turning. The result of turning the rotation (or vorticity) vector is the formation of *secondary flows*. The phenomenon must occur to some degree in all turbomachines, but is particularly in evidence in axial-flow compressors because of the thick boundary layers on the annulus walls. This case has been discussed in some detail by Horlock (1958), Preston (1953), Carter (1948), and many other writers.

Consider the flow at inlet to the guide vanes of a compressor to be completely axial and with a velocity profile as illustrated in Figure 6.16. This velocity profile is non-uniform as a result of friction between the fluid and the wall; the vorticity of this boundary layer is normal to the approach velocity c_1 and of magnitude

$$\omega_1 = \frac{dc_1}{dz}, \quad (6.51)$$

where z is distance from the wall.

The direction of ω_1 follows from the right-hand screw rule and it will be observed that ω_1 is in opposite directions on the two annulus walls. This vector is turned by the cascade, thereby generating *secondary vorticity* parallel to the outlet stream direction. If the deflection angle ε is not large, the magnitude of the secondary vorticity ω_s is, approximately,

$$\omega_s = -2\varepsilon \frac{dc_1}{dz}. \quad (6.52)$$

A swirling motion of the cascade exit flow is associated with the vorticity ω_s , as shown in Figure 6.17, which is in opposite directions for the two wall boundary layers. This secondary flow will be the *integrated* effect of the distribution of secondary vorticity along the blade length.

Now if the variation of c_1 with z is known or can be predicted, then the distribution of ω_s along the blade can be found using eqn. (6.52). By considering the secondary flow to be a small perturbation of

**FIGURE 6.16**

Secondary Vorticity Produced by a Row of Guide Vanes

**FIGURE 6.17**

Secondary Flows at Exit from a Blade Passage (Viewed in Upstream Direction)

the two-dimensional flow from the vanes, the flow angle distribution can be calculated using a series solution developed by Hawthorne (1955). The actual analysis lies outside the scope (and purpose) of this book, however. Experiments on cascade show excellent agreement with these calculations provided there are but small viscous effects and no flow separations. Such a comparison has been given by Horlock (1963) and a typical result is shown in Figure 6.18. It is clear that the flow is *overturned* near the walls and *underturned* some distance away from the walls. It is known that this overturning is a source of inefficiency in compressors as it promotes stalling at the blade extremities.

PROBLEMS

- Derive the radial equilibrium equation for an incompressible fluid flowing with axisymmetric swirl through an annular duct. Air leaves the inlet guide vanes of an axial flow compressor in radial equilibrium and with a free-vortex tangential velocity distribution. The absolute static pressure and static temperature at the hub, radius 0.3 m, are 94.5 kPa and 293 K, respectively. At the casing, radius 0.4 m, the absolute static pressure is 96.5 kPa. Calculate the flow angles at exit from the vanes at the hub and casing when the inlet absolute stagnation pressure is 101.3 kPa. Assume the fluid to be inviscid and incompressible. Take $R = 0.287 \text{ kJ/(kg}^\circ\text{C)}$ for air.

- A gas turbine stage has an initial absolute pressure of 350 kPa and a temperature of 565°C with negligible initial velocity. At the mean radius, 0.36 m, conditions are as follows:

Nozzle exit flow angle	68°
Nozzle exit absolute pressure	207 kPa
Stage reaction	0.2

Determine the flow coefficient and stage loading factor at the mean radius and the reaction at the hub, radius 0.31 m, at the design speed of 8000 rev/min, given that stage is to have a free-vortex swirl at this speed. You may assume that losses are absent. Comment upon the results you obtain. Take $C_p = 1.148 \text{ kJ/(kg}^\circ\text{C)}$ and $\gamma = 1.33$.

- Gas enters the nozzles of an axial flow turbine stage with uniform total pressure at a uniform velocity c_1 in the axial direction and leaves the nozzles at a constant flow angle α_2 to the axial direction. The absolute flow leaving the rotor c_3 is completely axial at all radii. Using radial equilibrium theory and assuming no losses in total pressure show that

$$(c_3^2 - c_1^2)/2 = U_m c_{\theta m2} \left[1 - \left(\frac{r}{r_m} \right)^{\cos^2 \alpha_2} \right],$$

where U_m is the mean blade speed, $c_{\theta m2}$ is the tangential velocity component at nozzle exit at the mean radius $r = r_m$. (Note: The approximate $c_3 = c_1$ at $r = r_m$ is used to derive this expression.)

4. Gas leaves an untwisted turbine nozzle at an angle α to the axial direction and in radial equilibrium. Show that the variation in axial velocity from root to tip, assuming total pressure is constant, is given by

$$c_x r^{\sin^2 \alpha} = \text{constant}.$$

Determine the axial velocity at a radius of 0.6 m when the axial velocity is 100 m/s at a radius of 0.3 m. The outlet angle α is 45° .

5. The flow at the entrance and exit of an axial-flow compressor rotor is in radial equilibrium. The distributions of the tangential components of absolute velocity with radius are

$$c_{\theta 1} = ar - b/r, \quad \text{before the rotor,}$$

$$c_{\theta 2} = ar + b/r, \quad \text{after the rotor,}$$

where a and b are constants. What is the variation of work done with radius? Deduce expressions for the axial velocity distributions before and after the rotor, assuming incompressible flow theory and that the radial gradient of stagnation pressure is zero. At the mean radius, $r = 0.3$ m, the stage loading coefficient, $\psi = \Delta W/U_t^2$ is 0.3, the reaction ratio is 0.5, and the mean axial velocity is 150 m/s. The rotor speed is 7640 rev/min. Determine the rotor flow inlet and outlet angles at a radius of 0.24 m given that the hub-tip ratio is 0.5. Assume that at the mean radius the axial velocity remained unchanged ($c_{x1} = c_{x2}$ at $r = 0.3$ m). (Note: ΔW is the specific work and U_t the blade tip speed.)

6. An axial-flow turbine stage is to be designed for free-vortex conditions at exit from the nozzle row and for zero swirl at exit from the rotor. The gas entering the stage has a stagnation temperature of 1000 K, the mass flow rate is 32 kg/s, the root and tip diameters are 0.56 m and 0.76 m, respectively, and the rotor speed is 8000 rev/min. At the rotor tip the stage reaction is 50% and the axial velocity is constant at 183 m/s. The velocity of the gas entering the stage is equal to that leaving. Determine

- (i) the maximum velocity leaving the nozzles;
- (ii) the maximum absolute Mach number in the stage;
- (iii) the root section reaction;
- (vi) the power output of the stage;
- (v) the stagnation and static temperatures at stage exit.

Take $R = 0.287$ kJ/(kg K) and $C_p = 1.147$ kJ/(kg K).

7. The rotor blades of an axial-flow turbine stage are 100 mm long and are designed to receive gas at an incidence of 3° from a nozzle row. A free-vortex whirl distribution is to be maintained between nozzle exit and rotor entry. At rotor exit the absolute velocity is 150 m/s in the axial direction at all radii. The deviation is 5° for the rotor blades and zero for the nozzle blades at all radii. At the hub, radius 200 mm, the conditions are as follows:

Nozzle outlet angle	70°
Rotor blade speed	180 m/s
Gas speed at nozzle exit	450 m/s

Assuming that the axial velocity of the gas is constant across the stage, determine

- (i) the nozzle outlet angle at the tip;
- (ii) the rotor blade inlet angles at hub and tip;
- (iii) the rotor blade outlet angles at hub and tip;
- (vi) the degree of reaction at root and tip.

Why is it essential to have a *positive* reaction in a turbine stage?

8. The rotor and stator of an isolated stage in an axial-flow turbomachine are to be represented by two actuator discs located at axial positions $x = 0$ and $x = \delta$, respectively. The hub and tip diameters are constant and the hub–tip radius ratio r_h/r_t is 0.5. The rotor disc considered on its own has an axial velocity of 100 m/s far upstream and 150 m/s downstream at a constant radius $r = 0.75r_t$. The stator disc in isolation has an axial velocity of 150 m/s far upstream and 100 m/s far downstream at radius $r = 0.75r_t$. Calculate and plot the axial velocity variation between $-0.5 \leq x/r_t \leq 0.6$ at the given radius for each actuator disc in isolation and for the combined discs when (i) $\delta = 0.1r_t$, (ii) $\delta = 0.25r_t$, (iii) $\delta = r_t$.

Centrifugal Pumps, Fans, and Compressors

And to thy speed add wings

Milton, *Paradise Lost*

7.1 INTRODUCTION

This chapter is concerned with the elementary flow analysis and preliminary design of *radial-flow* work-absorbing turbomachines comprising pumps, low speed fans, and compressors. The major part of the discussion is centred on the compressor since the basic action of all these machines is, in most respects, the same.

Turbomachines employing centrifugal effects for increasing fluid pressure have been in use for more than a century. The earliest machines using this method were hydraulic pumps followed later by ventilating fans and blowers. Cheshire (1945) recorded that a centrifugal compressor was incorporated in the build of the Whittle turbojet engine. Figure 7.1 is a version of this compressor illustrating, for that period, a rather complex flow path of the air. By way of contrast a modern centrifugal compressor is shown as one component of a composite compressor of a jet engine in Figure 7.2.

Development of the centrifugal compressor for aircraft propulsion continued into the mid-1950s but, long before this, it had become clear that axial flow compressors were better able to meet the needs of larger engines. Not only were the frontal area (and drag) smaller with engines using axial compressors but also the efficiency for the same duty was better by as much as 3 or 4%. However, for very small compressors with low flow rates, the efficiency of axial compressors drops sharply, blading is small and difficult to make accurately, and the centrifugal compressor is again the king. Many applications are found in small gas turbines for road vehicles and commercial helicopters as well as bigger applications, e.g., diesel engine turbochargers, chemical plant processes, factory workshop air supplies, large-scale air-conditioning plant, etc.

Centrifugal compressors were the choice for refrigerating plants and compression-type heat pumps used in district heating schemes described by Hess (1985). These compressors with capacities ranging from below 1 MW up to nearly 30 MW were preferred because of their good economy, low maintenance and absolute reliability.

Palmer and Waterman (1995) gave some details of an advanced two-stage centrifugal compressor used in a helicopter engine with a pressure ratio of 14, a mass flow rate of 3.3 kg/s, and an overall total-to-total efficiency of 80%. Both stages employed backswept vanes (approximately 47°) with a

**FIGURE 7.1**

A Version of the Centrifugal Compressor Used by Sir Frank Whittle (with Kind Permission of Rolls-Royce plc)

low aerodynamic loading achieved by having a relatively large number of vanes (19 full vanes and 19 splitter vanes). Some basic details are given in this chapter of calculating the performance of centrifugal compressors with backward swept impeller vanes. Figure 7.3 is a picture of a compressor that features a high performance centrifugal compressor impeller with 15 backswept main vanes (and 15 splitter vanes) and its surrounding wedge diffuser is fitted with 24 vanes.

An Axial-Radial Flow Compressor for Applications Requiring High Pressure Ratios and Intercooling (with Kind Permission of Siemens AG)

7.2 SOME DEFINITIONS

Most of the pressure-increasing turbomachines in use are of the radial-flow type and vary from fans that produce pressure rises equivalent to a few millimetres of water to pumps producing pressure heads of many hundreds of metres of water. The term *pump* refers to machines that increase the pressure of a flowing liquid. The term *fan* is used for machines imparting only a small increase in pressure to a flowing gas. In this case the pressure rise is usually so small that the gas can be considered as being incompressible. A *compressor* gives a substantial rise in pressure to a flowing gas. To make a distinction a compressor can be defined as a pressure-increasing machine where the *density ratio* across it is 1.05 or greater.

A centrifugal compressor or pump consists essentially of a rotating *impeller* followed by a *diffuser*. Figure 7.4 shows diagrammatically the various elements of a centrifugal compressor. Fluid is drawn in through the *inlet casing* into the *eye* of the impeller. The function of the impeller is to increase the energy level of the fluid by whirling it outwards, thereby increasing the angular momentum of the fluid. Both the static pressure and the velocity are increased within the impeller. The purpose of the diffuser is to convert the kinetic energy of the fluid leaving the impeller into pressure energy. This process can be accomplished by free diffusion in the annular space surrounding the impeller or, as indicated in Figure 7.4, by incorporating a row of fixed diffuser vanes that allows the diffuser to be made very much smaller. Outside the diffuser is a *scroll* or *volute* whose function is to collect the flow from the diffuser and deliver it to the outlet pipe. Often, in low speed compressors and pump applications where simplicity and low cost count for more than efficiency, the volute follows immediately after the impeller.

FIGURE 7.4

Centrifugal Compressor Stage and Velocity Diagrams at Impeller Entry and Exit

**FIGURE 7.5**

Radial-Flow Pump and Velocity Triangles

The *hub* is the curved surface of revolution of the impeller $a-b$; the *shroud* is the curved surface $c-d$ forming the outer boundary to the flow of fluid. At entry to the impeller the relative flow has a velocity w_1 at angle β_1 to the axis of rotation. This relative flow is turned into the axial direction by the *inducer section* or *rotating guide vanes* as they are sometimes called. The inducer starts at the eye and usually finishes in the region where the flow is beginning to turn into the radial direction. Some compressors of advanced design extend the inducer well into the radial flow region, apparently to reduce the amount of relative diffusion.

To simplify manufacture and reduce cost, *many fans and pumps* are confined to a two-dimensional radial section as shown in Figure 7.5. With this arrangement some loss in efficiency can be expected. For the purpose of greatest utility, relations obtained in this chapter are generally in terms of the three-dimensional compressor configuration.

7.3 THERMODYNAMIC ANALYSIS OF A CENTRIFUGAL COMPRESSOR

The flow through a centrifugal compressor stage is a highly complicated three-dimensional motion and a full analysis presents many problems. Fortunately, we can obtain approximate solutions by simplifying the flow model, e.g., by adopting the so-called *one-dimensional* approach that assumes that the fluid conditions are uniform over certain flow cross-sections. These cross-sections are conveniently taken immediately before and after the impeller as well as at inlet and exit of the entire machine. Where inlet vanes are used to give prerotation to the fluid entering the impeller, the one-dimensional treatment is no longer valid and an extension of the analysis is then required. (Examples of three-dimensional flows are given in Chapter 6.)

The Impeller

The general three-dimensional motion has components of velocity c_r , c_θ , and c_x , respectively, in the radial, tangential, and axial directions and $c^2 = c_r^2 + c_\theta^2 + c_x^2$.

From eqn. (1.20a), rothalpy can be rewritten as

$$I = h + \frac{1}{2}(c_r^2 + c_\theta^2 + c_x^2 - 2Uc_\theta).$$

Adding and subtracting $\frac{1}{2}U^2$ this becomes

$$I = h + \frac{1}{2}(U^2 - 2Uc_\theta + c_\theta^2) + \frac{1}{2}(c_r^2 + c_x^2 - U^2) = h + \frac{1}{2}(U - c_\theta)^2 + \frac{1}{2}(c_x^2 + c_r^2 - U^2). \quad (7.1)$$

From the velocity triangle, Figure 7.4, $U - c_\theta = w_\theta$, and with $w^2 = c_r^2 + w_\theta^2 + c_x^2$, eqn. (7.1) becomes

$$I = h + \frac{1}{2}(w^2 - U^2)$$

or

$$I = h_{0\text{rel}} - \frac{1}{2}U^2,$$

since $h_{0\text{rel}} = h + \frac{1}{2}w^2$. Across the impeller, $I_1 = I_2$ so

$$h_2 - h_1 = \frac{1}{2}(U_2^2 - U_1^2) + \frac{1}{2}(w_1^2 - w_2^2). \quad (7.2)$$

This expression provides the reason why the static enthalpy rise in a centrifugal compressor is so large compared with a single-stage axial compressor. On the right-hand side of eqn. (7.2), the second term, $\frac{1}{2}(w_1^2 - w_2^2)$, is the contribution from the diffusion of relative velocity, also obtained for axial compressors. The first term, $\frac{1}{2}(U_2^2 - U_1^2)$, is the contribution from the centrifugal action caused by the change in radius. The relation between the enthalpies at state points 1 and 2 can be traced in Figure 7.6 with the aid of eqn. (7.2).

Referring to Figure 7.4, and in particular the inlet velocity diagram, the absolute flow has no whirl component or angular momentum and $c_{\theta 1} = 0$. In centrifugal compressors and pumps this is the normal situation where the flow is free to enter axially. For such a flow the specific work done on the fluid, from eqn. (1.18b), is written as

$$\Delta W = U_2 c_{\theta 2} = h_{02} - h_{01} \quad (7.3)$$

in the case of compressors, and

$$\Delta W = U_2 c_{\theta 2} = gH_i \quad (7.4)$$

in the case of pumps, where H_i (the “ideal” head) is the total head rise across the pump *excluding all internal losses*. In high pressure ratio compressors it may be necessary to impart *prerotation* to the flow entering the impeller as a means of reducing a high relative inlet velocity. The effects of high relative velocity at the impeller inlet are experienced as Mach number effects in compressors and cavitation effects in pumps. The usual method of establishing prerotation requires the installation of a row of inlet guide vanes upstream of the impeller, the location depending upon the type of inlet. Unless contrary statements are made it will be assumed for the remainder of this chapter that there is no prerotation (i.e., $c_{\theta 1} = 0$).

**FIGURE 7.6**

Mollier Diagram for the Compressor Stage (Impeller and Diffuser Only)

The Diffuser

The diffuser is an important element of a compressor or pump. Its purpose is to reduce the velocity of the flow leaving the impeller resulting in an increase in pressure. The diffuser can be depicted as a channel *diverging* in the direction of flow (see Figure 7.7).

Although the basic diffuser appears to be a geometrically simple device it is beset by two serious fluid mechanical problems. The primary problem is the tendency of the boundary layers to separate from the diffuser walls if the local rate of diffusion is too rapid resulting in flow mixing and large losses in stagnation pressure. On the other hand, if the diffusion rate is too low, the fluid is exposed to a long length of wall and fluid friction losses again become excessive. Clearly, there has to be an *optimum rate of diffusion* between these two extremes for which the losses are minimised. Test results indicate that a diffuser with an included angle of about 7° or 8° gives the optimum recovery for both two-dimensional and conical diffusers.

Figure 7.8 shows the occurrence of flow unsteadiness or non-uniform flow at the exit from two-dimensional diffusers. The line marked *a-a* will be of most interest for turbomachinery diffuser applications. Note that this sharply marked transition line is not necessarily true and exact and a certain amount of arbitrariness and subjectivity attends the occurrence of “first stall.”

Some Diffuser Geometries and Their Notation: (a) Two-Dimensional and (b) Conical

FIGURE 7.8

Chart Depicting Flow Regimes for two-Dimensional Diffusers (Adapted from Sovran and Klomp, 1967)

**FIGURE 7.9**

Typical Diffuser Performance Curves for a Two-Dimensional Diffuser with $L/W_1 = 8.0$ (Adapted from Kline et al., 1959)

Figure 7.9 shows typical performance curves for a rectangular diffuser* with a fixed sidewall to length ratio, $L/W_1 = 8.0$, given by Kline, Abbott, and Fox (1959). On the line labeled C_p , points numbered 1, 2, and 3 are shown. These numbered points correspond to those shown in Figure 7.8 showing where they lie in relation to the various flow regimes. Inspection of the location of point 2 shows that optimum recovery at constant length occurs slightly above the line marked *No appreciable stall*. The performance of the diffuser between points 2 and 3 in Figure 7.9 shows a very significant deterioration and is in the regime of large amplitude, very unsteady flow.

7.4 DIFFUSER PERFORMANCE PARAMETERS

The diffusion process can be represented on a Mollier diagram, Figure 7.10, by a change of state from point 1 to point 2, and the corresponding changes in pressure from p_1 to p_2 and velocity from c_1 to c_2 .

Several ways are available for expressing diffuser performance in *compressible flow*:

- (i) Diffuser efficiency, η_D = ratio of actual change in enthalpy to the isentropic change in enthalpy. For steady and adiabatic flow in stationary passages, $h_{01} = h_{02}$, so that

$$h_2 = h_1 = \frac{1}{2}(c_1^2 - c_2^2). \quad (7.5a)$$

*This information will be referred to in Appendix B, "The Preliminary Design of a Centrifugal Compressor."

FIGURE 7.10

Mollier Diagram for a Diffuser Flow

For the equivalent reversible adiabatic process from state point 1 to state point 2_s ,

$$h_{2s} - h_1 = \frac{1}{2}(c_1^2 - c_{2s}^2). \quad (7.5b)$$

Hence,

$$\eta_D = (h_{2s} - h_1)/(h_2 - h_1) = (h_2 - h_1) = (c_1^2 - c_{2s}^2)/(c_1^2 - c_2^2). \quad (7.6)$$

- (ii) A total pressure recovery factor, p_{02}/p_{01} , can be used as a measure of diffuser performance. From eqn. (7.6) the diffuser efficiency is

$$\eta_D = (T_{2s}/T_1 - 1)/(T_2/T_1 - 1). \quad (7.7)$$

It may be more convenient to represent this efficiency in terms of pressure ratios as follows:

For the isentropic process $1 - 2s$,

$$\frac{T_{2s}}{T_1} = \left(\frac{p_2}{p_1}\right)^{(\gamma-1)/\gamma}.$$

For the constant temperature process, 01 – 02, we obtain $Tds = -dp/\rho$, which, when combined with the gas law, $p/\rho = RT$, gives $ds = -Rdp/p$. Upon integrating for the whole process we get

$$\Delta s = R \ln \left(\frac{p_{01}}{p_{02}} \right).$$

For the constant pressure process, 2s – 2, $Tds = dh = C_p dT$, therefore,

$$\Delta s = C_p \ln \left(\frac{T_2}{T_{2s}} \right).$$

Equating these expressions for the entropy increase and using $R/C_p = (\gamma - 1)/\gamma$, we find

$$\frac{T_2}{T_{2s}} = \left(\frac{p_{01}}{p_{02}} \right)^{(\gamma-1)/\gamma}.$$

Therefore,

$$\frac{T_2}{T_1} = \left(\frac{T_2}{T_{2s}} \right) \left(\frac{T_{2s}}{T_1} \right) = \left[\left(\frac{p_{01}}{p_{02}} \right) \left(\frac{p_2}{p_1} \right) \right]^{(\gamma-1)/\gamma}.$$

Substituting these expressions into eqn. (7.7) we get

$$\eta_D = \frac{(p_2/p_1)^{(\gamma-1)/\gamma} - 1}{[(p_{01}/p_{02})(p_2/p_1)]^{(\gamma-1)/\gamma} - 1}. \quad (7.8)$$

Example 7.1

Air enters the diffuser of a compressor with a velocity of 300 m/s at a stagnation pressure of 200 kPa and a stagnation temperature of 200°C and leaves the diffuser with a velocity of 50 m/s. Using compressible flow relations and assuming the diffuser efficiency, $\eta_D = 0.9$, determine

- (i) the static temperatures at inlet and outlet of the diffuser and the inlet Mach number;
- (ii) the static pressure at diffuser inlet;
- (iii) the increase in entropy caused by the diffusion process.

Take $\gamma = 1.4$ and $C_p = 1005 \text{ J/kg K}$

Solution

Note: When solving diffuser problems it is advisable and always useful to make a sketch of the Mollier diagram of the diffusion process. In this case we refer to Figure 7.10.

The expression for the diffuser efficiency, which is most useful for this example, is eqn. (7.7):

$$\eta_D = (T_{2s}/T_1 - 1)/(T_2/T_1 - 1).$$

From the energy equation, $h_{01} - h_1 = \frac{1}{2}c_1^2$ we obtain,

$$\frac{T_1}{T_{01}} = 1 - \frac{c_1^2}{2C_p T_{01}} = 1 - \frac{300^2}{2 \times 1005 \times 473} = 0.90533.$$

Therefore,

$$T_1 = 428.2 \text{ K as } T = 473 \text{ K.}$$

The Mach number at diffuser entry is

$$M_1 = c_1/a_1 \text{ where } a_1 = \sqrt{\gamma RT_1} = \sqrt{1.4 \times 287 \times 428.2} = 414.8 \text{ m/s.}$$

Therefore,

$$M_1 = 0.7233.$$

Again, from the energy equation, $h_{02} - h_2 = \frac{1}{2}c_2^2$, hence,

$$\frac{T_2}{T_{02}} = 1 - \frac{c_2^2}{2C_p T_{02}} = 1 - \frac{50^2}{2 \times 1050 \times 473} = 0.9974$$

and

$$T_2 = 471.7 \text{ K.}$$

From the diffuser efficiency definition above, we get

$$\frac{T_{2s}}{T_1} = \eta_D \left(\frac{T_2}{T_1} - 1 \right) + 1 = 1 + 0.9 \left(\frac{471.7}{428.2} - 1 \right) = 1.0915,$$

$$\frac{p_2}{p_1} = \left(\frac{T_{2s}}{T_1} \right)^{\gamma/(\gamma-1)} = 1.0915^{3.5} = 1.3588,$$

$$\frac{p_{01}}{p_1} = \left(\frac{T_{02}}{T_1} \right)^{\gamma/(\gamma-1)} = \left(\frac{473}{428.2} \right)^{3.5} = 1.4166.$$

Therefore,

$$p_1 = 141.2 \text{ kPa}$$

and

$$p_2 = 1.3588 \times 141.2 = 191.8 \text{ kPa.}$$

From the thermodynamic relation, namely $Tds = dh - \frac{1}{\rho}dp$, we obtain

$$s_2 - s_1 = C_p \ln \frac{T_2}{T_1} - R \ln \frac{p_2}{p_1} = 1005 \ln \frac{471.7}{428.2} - 287 \ln 1.3588 = 97.2 - 88.0 = 9.2 \text{ J/kg K.}$$

For *incompressible flow* ($\rho = \text{constant}$) several expressions for performance parameters can be obtained in terms of the pressure differences:

$$h_{2s} - h_1 = (p_2 - p_1)/\rho,$$

so that the diffuser efficiency can be written as

$$\eta_D = 2(p_2 - p_1) / \rho(c_1^2 - c_2^2). \quad (7.9)$$

A *pressure rise coefficient* C_p can be defined

$$C_p = (p_2 - p_1) / q_1, \quad (7.10)$$

where $q_1 = \frac{1}{2}\rho c_1^2$.

The energy equation for the diffuser is

$$p_1/\rho + \frac{1}{2}c_1^2 = p_2/\rho + \frac{1}{2}c_2^2 + \Delta p_0/\rho, \quad (7.11)$$

where $\Delta p_0 = p_{01} - p_{02}$ is the loss in total pressure in the diffuser. From the continuity equation

$$c_1/c_2 = A_2/A_1 = A_R. \quad (7.12)$$

From eqn. (7.11), with $\Delta p_0 = 0$, an *ideal pressure rise coefficient*, $C_{p,id}$, can be defined

$$C_{p,id} = 1 - (c_2/c_1)^2 = 1 - (1/A_R^2). \quad (7.13)$$

Thus, eqn. (7.10) can be written as

$$C_p = C_{p,id} - \Delta p_0 / q_1. \quad (7.14)$$

The diffuser efficiency is simply

$$\eta_D = C_p / C_{p,id}. \quad (7.15)$$

7.5 INLET VELOCITY LIMITATIONS AT THE EYE

The inlet eye is an important and critical region in both centrifugal pumps and compressors and requires careful consideration at the design stage. If the relative velocity of the inlet flow is too large in pumps, cavitation (details in next section) may result with consequent blade erosion or even reduced performance. In compressors large relative velocities can cause an increase in the impeller total pressure losses. In high speed centrifugal compressors Mach number effects may become important with high relative velocities in the inlet. By suitable sizing of the eye the maximum relative velocity, or some related parameter (e.g., maximum relative Mach number), can be minimised to give the optimum inlet flow conditions. As an illustration the following analysis shows a simple optimization procedure for a low speed compressor based upon incompressible flow theory.

For the inlet geometry shown in Figure 7.4, the absolute eye velocity is assumed to be uniform and axial. The inlet relative velocity is $w_1 = (c_{x1}^2 + U^2)^{1/2}$, which, of course, is a maximum at the inducer's tip. The volume flow rate is

$$Q = c_{x1}A_1 = \pi(r_{s1}^2 - r_{h1}^2)(w_{s1}^2 - \Omega^2 r_{s1}^2)^{1/2}. \quad (7.16)$$

It is worth noticing that with both Q and r_{h1} are fixed

- (i) if r_{s1} is made large then, from continuity, the axial velocity is low but the blade speed is high;
- (ii) if r_{s1} is made small the blade speed is small but the axial velocity is high.

Both extremes produce large relative velocities and there must exist some optimum radius r_{s1} for which the relative velocity is a minimum.

For maximum volume flow, differentiating eqn. (7.16) with respect to r_{s1} (keeping w_{s1} constant) and equate to zero,

$$\frac{1}{\pi} \frac{\partial Q}{\partial r_{s1}} = 0 = 2r_{s1}(w_{s1}^2 - \Omega^2 r_{s1}^2)^{1/2} - (r_{s1}^2 - r_{h1}^2)\Omega^2 r_{s1}^2 / (w_{s1}^2 - \Omega^2 r_{s1}^2)^{1/2}.$$

After simplifying,

$$2(w_{s1}^2 - \Omega^2 r_{s1}^2) = (r_{s1}^2 - r_{h1}^2)\Omega^2;$$

therefore,

$$2c_{x1}^2 = kU_{s1}^2, \quad (7.17)$$

where $k = 1 - (r_{h1}/r_{s1})^2$ and $U_{s1} = \Omega r_{s1}$. Hence, the optimum inlet velocity coefficient is

$$\phi = c_{x1}/U_{s1} = \cot \beta_{s1} = (k/2)^{1/2}. \quad (7.18)$$

Equation (7.18) specifies the optimum conditions for the inlet velocity triangles in terms of the hub-tip radius ratio. For typical values of this ratio (i.e., $0.3 \leq r_{h1}/r_{s1} \leq 0.6$) the optimum relative flow angle at the inducer tip β_{s1} lies between 56° and 60° .

7.6 OPTIMUM DESIGN OF A PUMP INLET

As discussed in Chapter 2, cavitation commences in a flowing liquid when the decreasing local static pressure becomes approximately equal to the vapour pressure, p_v . To be more precise, it is necessary to assume that gas cavitation is negligible and that sufficient *nuclei* exist in the liquid to initiate *vapour cavitation*.

The pump considered in the following analysis is again assumed to have the flow geometry shown in Figure 7.4. Immediately upstream of the impeller blades the static pressure is $p_1 = p_{01} - \frac{1}{2}\rho c_{x1}^2$ where p_{01} is the stagnation pressure and c_{x1} is the axial velocity. In the vicinity of the impeller blades leading edges on the suction surfaces there is normally a rapid velocity increase that produces a further decrease in pressure. At cavitation inception the dynamic action of the blades causes the *local* pressure to reduce such that $p = p_v = p_1 - \sigma_b(\frac{1}{2}\rho w_1^2)$. The parameter σ_b is the *blade cavitation coefficient* corresponding to the cavitation inception point and depends upon the blade shape and the flow incidence angle. For conventional pumps (Pearsall, 1972) that operate normally, this coefficient lies in the range $0.2 \leq \sigma_b \leq 0.4$. Thus, at cavitation inception

$$p_1 = p_{01} - \frac{1}{2}\rho c_{x1}^2 = p_v + \sigma_b \left(\frac{1}{2}\rho w_1^2 \right),$$

therefore

$$gH_s = (p_{01} - p_v)/\rho = \frac{1}{2}c_{x1}^2 + \sigma_b \left(\frac{1}{2}w_1^2 \right) = \frac{1}{2}c_{x1}^2(1 + \sigma_b) + \frac{1}{2}\sigma_b U_{s1}^2,$$

where H_s is the net positive suction head introduced earlier and it is implied that this is measured at the shroud radius $r = r_{s1}$.

To obtain the optimum inlet design conditions consider the suction specific speed, defined as $\Omega_{ss} = \Omega Q^{1/2} / (gH_s)^{3/4}$, where $\Omega = U_{s1}/r_{s1}$ and $Q = c_{x1}A_1 = \pi k r_{s1}^2 c_{x1}$. Thus,

$$\frac{\Omega_{ss}^2}{\pi k} = \frac{U_{s1}^2 c_{x1}}{[\frac{1}{2}c_{x1}^2(1 + \sigma_b) + \frac{1}{2}\sigma_b U_{s1}^2]^{3/2}} = \frac{\phi}{[\frac{1}{2}(1 + \sigma_b)\phi^2 + \frac{1}{2}\sigma_b]^{3/2}}, \quad (7.19)$$

where $\phi = c_{x1}/U_{s1}$. To obtain the condition of maximum Ω_{ss} , eqn. (7.19) is differentiated with respect to ϕ and the result set equal to zero. From this procedure the optimum conditions are found:

$$\phi = \left\{ \frac{\sigma_b}{2(1 + \sigma_b)} \right\}^{1/2}, \quad (7.20a)$$

$$gH_s = \frac{3}{2}\sigma_b \left(\frac{1}{2}U_{s1}^2 \right), \quad (7.20b)$$

$$\Omega_{ss}^2 = \frac{2\pi k(2/3)^{1.5}}{\sigma_b(1 + \sigma_b)^{0.5}} = \frac{3.420k}{\sigma_b(1 + \sigma_b)^{0.5}}. \quad (7.20c)$$

Example 7.2

The inlet of a centrifugal pump of the type shown in Figure 7.4 is to be designed for optimum conditions when the flow rate of water is 25 dm³/s and the impeller rotational speed is 1450 rev/min. The maximum suction specific speed $\Omega_{ss} = 3.0$ (rad) and the inlet eye radius ratio is to be 0.3. Determine

- (i) the blade cavitation coefficient;
- (ii) the shroud diameter at the eye;
- (iii) the eye axial velocity;
- (iv) the net positive suction head (NPSH).

Solution

- (i) From eqn. (7.20c), squaring both sides,

$$\sigma_b^2(1 + \sigma_b) = (3.42k)^2 / \Omega_{ss}^4 = 0.1196,$$

with $k = 1 - (r_{h1}/r_{s1})^2 = 1 - 0.3^2 = 0.91$. Solving iteratively (e.g., using the Newton–Raphson approximation), we get $\sigma_b = 0.3030$.

- (ii) As $Q = \pi k r_{s1}^2 c_{x1}$ and $c_{x1} = \phi r_{s1} \Omega$, $r_{s1}^3 = Q / (\pi k \Omega \phi)$ and, hence, $\Omega = 1450\pi/30 = 151.84$ rad/s. From eqn. (7.20a), $\phi = [0.303/(2 \times 1.303)]^{0.5} = 0.3410$,

$$r_{s1}^3 = 0.025 / (\pi \times 0.91 \times 151.84 \times 0.341) = 1.689 \times 10^{-4},$$

$$r_{s1} = 0.05528 \text{ m.}$$

The required diameter of the eye is 110.6 mm.

(iii) $c_{x1} = \phi \Omega r_{s1} = 0.341 \times 151.84 \times 0.05528 = 2.862 \text{ m/s}$.

(iv) From eqn. (7.20b), the *net positive suction head* (NPSH) is

$$H_s = \frac{0.75 \sigma_b c_{x1}^2}{g \phi^2} = \frac{0.75 \times 0.303 \times 2.862^2}{9.81 \times 0.341^2} = 1.632 \text{ m}.$$

7.7 OPTIMUM DESIGN OF A CENTRIFUGAL COMPRESSOR INLET

To obtain high efficiencies from high pressure ratio compressors it is necessary to limit the relative Mach number at the eye. In the following paragraphs two analyses are given, the first for an axial flow at inlet, $\alpha_1 = 0^\circ$, and the second when prewhirl vanes are used and $\alpha_1 > 0^\circ$. The analyses are applied to the shroud radius r_{s1} at the impeller eye.

Case A ($\alpha_1 = 0^\circ$)

The flow area at the eye is

$$A_1 = \pi r_{s1}^2 k,$$

where $k = 1 - (r_{h1}/r_{s1})^2$. Hence,

$$A_1 = \pi k U_{s1}^2 / \Omega^2 \quad (7.21)$$

with $U_{s1} = \Omega r_{s1}$. Assuming a uniform axial velocity, the continuity equation is, $\dot{m} = \rho_1 A_1 c_{x1}$.

From the inlet velocity diagram (Figure 7.4), $c_{x1} = w_{s1} \cos \beta_{s1}$ and $U_{s1} = w_{s1} \sin \beta_{s1}$. Using eqn. (7.21),

$$\frac{\dot{m} \Omega^2}{\rho_1 k \pi} = w_{s1}^3 \sin^2 \beta_{s1} \cos \beta_{s1}. \quad (7.22)$$

For a perfect gas the static density ρ is

$$\rho = \rho_0 \left(\frac{p}{p_0} \right) \left(\frac{T_0}{T} \right).$$

With $C_p T_0 = C_p T + \frac{1}{2} c^2$ and $C_p = \gamma R / (\gamma - 1)$,

$$\frac{T_0}{T} = 1 + \frac{\gamma - 1}{2} M^2 = \frac{a_0^2}{a^2},$$

where the Mach number, $M = c / (\gamma R T)^{1/2} = c / a$, a_0 and a being the stagnation and local (static) speeds of sound. For isentropic flow,

$$\frac{p}{p_0} = \left(\frac{T}{T_0} \right)^{\gamma / (\gamma - 1)}.$$

Thus,

$$\frac{\rho_1}{\rho_0} = \left(\frac{T_1}{T_0} \right)^{1 - \gamma / (\gamma - 1)} = \left(1 + \frac{\gamma - 1}{2} M_1^2 \right)^{-1 / (\gamma - 1)},$$

where $\rho_0 = p_0 / (R T_0)$.

The absolute Mach number M_1 and the relative Mach number $M_{1,rel}$ are defined as

$$M_1 = c_{x1}/a_1 = M_{1,rel} \cos \beta_{s1} \text{ and } w_{s1} = M_{1,rel} a_1.$$

Using these two relations together with eqn. (7.10) we obtain

$$\frac{\dot{m} \Omega^2 R T_{01}}{k \pi p_{01}} = \frac{M_{1,rel}^3 a_1^3}{\left[1 + \frac{1}{2}(\gamma - 1) M_1^2\right]^{1/(\gamma-1)}} \sin^2 \beta_{s1} \cos \beta_{s1}.$$

Since $a_{01}/a_1 = \left[1 + \frac{1}{2}(\gamma - 1) M_1^2\right]^{1/2}$ and $a_{01} = (\gamma R T_{01})^{1/2}$ this equation is reworked to give

$$\frac{\dot{m} \Omega^2}{\gamma \pi k p_{01} (\gamma R T_{01})^{1/2}} = \frac{M_{1,rel}^3 \sin^2 \beta_{s1} \cos \beta_{s1}}{\left[1 + \frac{1}{2}(\gamma - 1) M_{1,rel}^2 \cos^2 \beta_{s1}\right]^{1/(\gamma-1)+3/2}}. \quad (7.23a)$$

Although it looks cumbersome the preceding equation is really quite useful. For a particular gas, by specifying values of γ , R , p_{01} , and T_{01} , we obtain $\dot{m} \Omega^2 / k$ as a function of $M_{1,rel}$ and β_{s1} . Choosing a particular value of $M_{1,rel}$ as a limit, an optimum value of β_{s1} for *maximum mass flow* can then be found.

Taking air as an example and assuming $\gamma = 1.4$, eqn. (7.23a) becomes

$$f(M_{1,rel}, \beta_{s1}) = \dot{m} \Omega^2 / (1.4 \pi k p_{01} a_{01}) = \frac{M_{1,rel}^3 \sin^2 \beta_{s1} \cos \beta_{s1}}{\left(1 + \frac{1}{5} M_{1,rel}^2 \cos^2 \beta_{s1}\right)^4}. \quad (7.24a)$$

The right-hand side of eqn. (7.24a) is plotted in Figure 7.11 as a function of β_{s1} for $M_{1,rel} = 0.8$ and 0.9 . It can be shown that these curves are a maximum when

$$\cos^2 \beta_{s1} = A - \sqrt{A^2 - 1/M_{1,rel}^2},$$

where $A = 0.7 + 1.5/M_{1,rel}^2$.

Case B ($\alpha_1 > 0^\circ$)

The effect of prewhirl on the mass flow function can be determined by a similar analysis. From the velocity triangles in Figure 7.4,

$$c_1 = c_x / \cos \alpha_1 = w_1 \cos \beta_1 / \cos \alpha_1,$$

$$\dot{m} = \rho A c_r = 2 \pi r b \rho c_r$$

Also, $U_1 = w_1 \sin \beta_1 + c_1 \sin \alpha_1 = w_1 \cos \beta_1 (\tan \beta_1 + \tan \alpha_1)$,

$$\dot{m} = \rho_1 A_1 c_{x1}.$$

It is better to refer to the shroud radius r_{s1} from this point on. Following the previous procedure we get

$$\dot{m} = \frac{\pi k}{\Omega^2} \rho_1 U_{s1}^2 w_{s1} \cos \beta_{s1} = \left(\frac{\pi k \rho_1}{\Omega^2}\right) w_1^3 \cos^3 \beta_{s1} (\tan \beta_{s1} + \tan \alpha_{s1})^2.$$

Using the relations developed earlier for T_{01}/T_1 , p_{01}/p_1 , and ρ_{01}/ρ_1 , we obtain

$$f(M_{1,rel}, \beta_{s1}) = \frac{\dot{m} \Omega^2}{\pi k \rho_{01} a_{01}^3} = \frac{M_{1,rel}^3 \cos^3 \beta_{s1} (\tan \beta_{s1} + \tan \alpha_{s1})^2}{\left(1 + \frac{\gamma-1}{2} M_{1,rel}^2 \cos^2 \beta_{s1} / \cos^2 \alpha_{s1}\right)^{\frac{1}{\gamma-1} + \frac{3}{2}}}. \quad (7.23b)$$

FIGURE 7.11

Variation of Mass Flow Function $f(M_{1,rel})$ as a Function of β_{s1} for the Inducer of a Centrifugal Compressor: Case A, No Guide Vanes, $\alpha_1 = 0$, Case B, with Guide Vanes, $\alpha_1 > 0$.

Substituting $\gamma = 1.4$ for air into eqn. (7.12) we get

$$f(M_{1,rel}) = \frac{\Omega^2 \dot{m}}{\pi k \rho_{01} a_{01}^3} = \frac{M_{1,rel}^3 \cos^3 \beta_{s1} (\tan \beta_{s1} + \tan \alpha_{s1})^2}{\left(1 + \frac{1}{5} M_{1,rel}^2 \cos^2 \beta_{s1} / \cos^2 \alpha_{s1}\right)^4}. \quad (7.24b)$$

The right-hand side of eqn. (7.24b) is plotted in Figure 7.11 with $\alpha_1 = 30^\circ$ and $M_{1,rel} = 0.8$ and 0.9 , showing that the peak values of $\dot{m} \Omega^2 / k$ are significantly increased but arise at much lower values of β_{s1} .

Example 7.3

The inlet of a centrifugal compressor is fitted with free-vortex guide vanes to provide a positive prewhirl of 30° at the shroud. The inlet hub–shroud radius ratio is 0.4 and a requirement of the design is that the relative inlet Mach number, $M_{1,rel}$, does not exceed 0.9 . The air mass flow is 1 kg/s , the stagnation pressure and temperature are 101.3 kPa and 288 K . For air take $R = 287 \text{ J/(kgK)}$ and $\gamma = 1.4$.

Assuming optimum conditions at the shroud, determine

- the rotational speed of the impeller;
- the inlet static density downstream of the guide vanes at the shroud and the axial velocity;
- the inducer tip diameter and velocity.

Solution

- (i) From Figure 7.9, the peak value of $f(M_{1,\text{rel}}) = 0.4307$ at a relative flow angle $\beta_1 = 49.4^\circ$. The constants needed are $a_{01}\sqrt{\gamma RT_{01}} = 340.2$ m/s, $\rho_{01} = p_{01}/RT_{01} = 1.2255$ kg/m³, and $k = 1 - 0.4^2 = 0.84$. From eqn. (7.24b), we find $\Omega^2 = \pi f k \rho_{01} a_{01}^3 = 5.4843 \times 10^7$. Hence,

$$\Omega = 7405.6 \text{ rad/s and } N = 70,718 \text{ rev/min.}$$

$$(ii) \quad \rho_1 = \frac{\rho_{01}}{\left[1 + \frac{1}{5}(M_{1,\text{rel}} \cos \beta_1)^2\right]^{2.5}} = \frac{1.2255}{1.06973^{2.5}} = 0.98464 \text{ kg/m}^3.$$

The axial velocity is found from

$$(w_1 \cos \beta_1)^3 = c_x^3 = \frac{\Omega^2 \dot{m}}{\pi k \rho_1 (\tan \beta_1 + \tan \alpha_1)^2} = \frac{5.4843 \times 10^7}{\pi \times 0.84 \times 0.98464 \times 3.0418} = 6.9388 \times 10^6,$$

therefore,

$$c_x = 190.73 \text{ m/s.}$$

$$(iii) \quad A_1 = \frac{\dot{m}}{\rho_1 c_x} = \pi k r_{s1}^2,$$

therefore,

$$r_{s1}^2 = \frac{\dot{m}}{\pi \rho_1 c_x k} = \frac{1}{\pi \times 0.98464 \times 190.73 \times 0.84} = 2.0178 \times 10^{-3},$$

$$r_{s1} = 0.04492 \text{ m and } d_{s1} = 8.984 \text{ cm,}$$

$$U = \Omega r_{s1} = 7405.6 \times 0.04492 = 332.7 \text{ m/s.}$$

Some Remarks on the Use of Preshirl Vanes at Entry to the Impeller

Introducing positive preshirl (i.e., in the direction of impeller rotation) can give a significant reduction of w_1 and the inlet Mach number $M_{1,\text{rel}}$ but, as can be seen from the Euler pump equation, eqn. (1.18b), it reduces the specific work done on the gas. Thus, it is necessary to increase the blade tip speed to maintain the same level of impeller pressure ratio as was obtained without preshirl.

Preshirl is obtained by fitting guide vanes upstream of the impeller. One arrangement for doing this is shown in Figure 7.12(a). The velocity triangles, Figures 7.12(b) and 7.12(c), suggest how the guide vanes reduce the relative inlet velocity. Guide vanes are designed to produce either a free-vortex or some form of forced-vortex velocity distribution. In Chapter 6 it was shown that for a free-vortex flow ($rc_\theta = \text{constant}$) the axial velocity c_x is constant (in the ideal flow). It was shown by Wallace, Whitfield, and Atkey (1975) that the use of free-vortex preshirl vanes leads to a significant increase in incidence angle with low inducer radius ratios. The use of some forced-vortex velocity distribution does alleviate this problem. Whitfield and Baines (1990) have reviewed some of the effects resulting

**FIGURE 7.12**

Effect of Free-Vortex Prewhirl Vanes upon the Relative Velocity at Impeller Inlet

from the adoption of various forms of a *generalised forced-vortex*,

$$c_\theta = A \left(\frac{r}{r_{s1}} \right)^n, \quad (7.25)$$

where n is any integer value in the range -1 to 2 .

Figure 7.13(a) shows (for a particular case in which $\alpha_{s1} = 30^\circ$, $\beta_{s1} = 60^\circ$) the effect of prewhirl on the variation of the incidence angle, $i = \beta_1 - \beta'_2$ with radius ratio, r/r_{s1} , for several whirl distributions. Figure 7.13(b) shows the corresponding variations of the absolute flow angle, α_1 . It is apparent that a high degree of prewhirl vane twist is required for either a free-vortex design or for the quadratic ($n = 2$) design. The advantage of the quadratic design is the low variation of incidence with radius, whereas it is evident that the free-vortex design produces a wide variation of incidence. Wallace et al. (1975) adopted the simple untwisted blade shape ($n = 0$), which proved to be a reasonable compromise.

7.8 SLIP FACTOR

Introduction

Even under ideal (i.e., frictionless) conditions the relative flow leaving the impeller of a compressor or pump will receive less than perfect guidance from the vanes and the real flow is said to *slip*. If the impeller could be imagined as being made with an infinite number of infinitesimally thin vanes, then an ideal flow would be perfectly guided by the vanes and would leave the impeller at the vane angle. Figure 7.14 compares the relative flow angle, β_2 , obtained with a finite number of vanes, with the vane angle, β'_2 .

**FIGURE 7.13**

Effect of Preshirl Vanes on (a) Incidence Angle and (b) Absolute Flow Angle with $\alpha_{s1} = 30^\circ$, $\beta_{s1} = 60^\circ$

**FIGURE 7.14**

Effect of Slip (in the Velocity Diagram) on the Relative Flow Angle β_2 at Exit from an Impeller with Backswept Vanes at a Vane Angle of β_2'

A slip factor may be defined as

$$\sigma = c_{\theta 2} / c_{\theta 2}', \quad (7.26a)$$

where $c_{\theta 2}$ is the tangential component of the absolute velocity and related to the relative flow angle β_2 . The hypothetical tangential velocity component $c_{\theta 2}'$ is related to the vane angle β_2' . The slip velocity is given by $c_{\theta s} = c_{\theta 2}' - c_{\theta 2}$ so that the slip factor can be written as

$$\sigma = 1 - c_{\theta s} / c_{\theta 2}'. \quad (7.26b)$$

The slip factor is a vital piece of information needed by pump and compressor designers (also by designers of radial turbines as it turns out!) as its accurate estimation enables finding the correct

value of the energy transfer between impeller and fluid. Various attempts to determine values of slip factor have been made and numerous research papers concerned solely with this topic have been published. Wiesner (1967) has given an extensive review of the various expressions used for determining slip factors. Most of the expressions derived relate to radially vaned impellers ($\beta'_2 = 0$) or to mixed flow designs, but some are given for *backward swept vane* (bsv) designs. All of these expressions are derived from inviscid flow theory even though the real flow is far from ideal. However, despite this apparent lack of a realistic touch in the flow modelling, the fact remains that good results are still obtained with the various theories.

The Relative Eddy Concept

Suppose that an irrotational and frictionless fluid flow is possible that passes through an impeller. If the absolute flow enters the impeller without spin, then at outlet the spin of the absolute flow *must still be zero*. The impeller itself has an angular velocity Ω so that, relative to the impeller, the fluid has an angular velocity of $-\Omega$; this is termed the *relative eddy*. A simple explanation for the slip effect in an impeller is obtained from the idea of a relative eddy.

At outlet from the impeller the relative flow can be regarded as a through-flow on which is superimposed a relative eddy. The net effect of these two motions is that the average relative flow emerging from the impeller passages is at an angle to the vanes and in a direction opposite to the blade motion, as indicated in Figure 7.15. This is the basis of the various theories of slip.

Slip Factor Correlations

One of the earliest and simplest expressions for the slip factor was obtained by Stodola (1945). Referring to Figure 7.16 the *slip velocity*, $c_{\theta s} = c_{\theta 2'} - c_{\theta 2}$, is considered to be the product of the relative eddy and the radius $d/2$ of a circle, which can be inscribed within the channel. Thus, $c_{\theta s} = \Omega d/2$. If the number of vanes is denoted by Z then an approximate expression, $d \cong (2\pi r_2/Z)\cos\beta'_2$, can be written if Z is not small. Since $\Omega = U_2/r_2$,

FIGURE 7.15

(a) Relative Eddy without Any Through-Flow; (b) Relative Flow at Impeller Exit (Through-Flow Added to Relative Eddy)

**FIGURE 7.16**

Flow Model used by Stodola for His Slip Factor

$$c_{\theta s} = \frac{\pi U_2 \cos \beta'_2}{Z}. \quad (7.26c)$$

Now as $c'_{\theta 2} = U_2 - c_{r2} \tan \beta'_2$ the Stodola slip factor becomes

$$\sigma = \frac{c_{\theta 2}}{c'_{\theta 2}} = 1 - \frac{c_{\theta s}}{U_2 - c_{r2} \tan \beta'_2} \quad (7.27)$$

or

$$\sigma = 1 - \frac{(\pi/Z) \cos \beta'_2}{1 - \phi_2 \tan \beta'_2}. \quad (7.28)$$

where $\phi_2 = c_{r2}/U_2$.

A number of “mathematically exact” solutions have been evolved of which the best known is that of Busemann (1928). This theory applies to the special case of two-dimensional vanes curved as logarithmic spirals as shown in Figure 7.17.

Considering the geometry of the vane element shown it can be proved that

$$\kappa = \tan \beta' \ln(r_2/r_1) \quad (7.29)$$

and that the ratio of vane length to equivalent blade pitch is

$$\frac{l}{s} = \frac{Z}{2\pi \cos \beta'} \ln \left(\frac{r_2}{r_1} \right). \quad (7.30)$$

FIGURE 7.17

Logarithmic Spiral Vane; Vane Angle β' Is Constant for All Radii

Hence, the equivalent pitch is

$$s = \frac{2\pi(r_2 - r_1)}{Z \ln(r_2/r_1)}. \quad (7.31)$$

The equiangular or logarithmic spiral is the simplest form of radial vane system and has been frequently used for *pump impellers* in the past. The Busemann slip factor can be written as

$$\sigma = (A - B\phi_2 \tan \beta'_2) / (1 - \phi_2 \tan \beta'_2). \quad (7.32)$$

where both A and B are functions of r_2/r_1 , β'_2 , and Z . For typical pump and compressor impellers the dependence of A and B on r_2/r_1 is negligible when the equivalent l/s exceeds unity. From eqn. (7.30) the requirement for $l/s \geq 1$, is that the radius ratio must be sufficiently large, i.e.,

$$r_2/r_1 \geq \exp(2\pi \cos \beta'_2/Z). \quad (7.33)$$

This criterion is often applied to other than logarithmic spiral vanes, then β'_2 is used instead of β' . Radius ratios of typical centrifugal pump impeller vanes normally exceed the preceding limit. For instance, blade outlet angles of impellers are usually in the range $50^\circ \leq \beta'_2 \leq 70^\circ$ with between 5 and 12 vanes. Taking representative values of $\beta'_2 = 60^\circ$ and $Z = 8$ the right-hand side of eqn. (7.33) is equal to 1.48, which is not particularly large for a pump.

So long as these criteria are obeyed the value of B is constant and practically equal to unity for all conditions. Similarly, the value of A is independent of the radius ratio r_2/r_1 and depends on β'_2 and Z only. Values of A given by Csanady (1960) are shown in Figure 7.18 and may also be interpreted as the value of σ_B for zero through-flow ($\phi_2 = 0$).

The exact solution of Busemann makes it possible to check the validity of approximate methods of calculation, such as the Stodola expression. By putting $\phi_2 = 0$ in eqns. (7.28) and (7.32) a comparison of the Stodola and Busemann slip factors at the zero through-flow condition can be made. The Stodola

**FIGURE 7.18**

Head Correction Factors for Centrifugal Impellers (Adapted from Csanady, 1960)

value of slip comes close to the exact correction if the vane angle is within the range $50^\circ \leq \beta'_2 \leq 70^\circ$ and the number of vanes exceeds six.

Stanitz (1952) applied the mathematical method called *relaxation* to solve the potential flow field between the blades of eight impellers with blade tip angles β'_2 varying between 0° and 45° . The conclusions drawn were that the computed slip velocity $c_{\theta s}$ was independent of vane angle β'_2 and depended only on blade spacing (number of blades). He also found that compressibility effects did not affect the slip factor. Stanitz's expression for slip velocity is

$$c_{\theta s} = 0.63 U_2 \pi / Z, \quad (7.34a)$$

and it is easily shown that the corresponding slip factor using eqn. (7.27) is

$$\sigma = 1 - \frac{0.63\pi/Z}{1 - \phi_2 \tan \beta'_2}. \quad (7.34b)$$

For radial vaned impellers this becomes $\sigma = 1 - 0.63\pi/Z$ but is often written for initial approximate calculations as $\sigma = 1 - 2/Z$.

Wiesner (1967) reviewed all available methods and concluded that Busemann's procedure was still the most generally applicable predictor for determining the slip factor of centripetal impellers. Wiesner obtained the following simple empirical expression for the slip velocity,

$$c_{\theta s} = \frac{U_2 \sqrt{\cos \beta'_2}}{Z^{0.7}}. \quad (7.35a)$$

and the corresponding slip factor,

$$\sigma = 1 - \frac{\sqrt{\cos \beta'_2 / Z^{0.7}}}{(1 - \phi_2 \tan \beta'_2)}, \quad (7.35b)$$

which, according to Wiesner, fitted the Busemann results “extremely well over the whole range of practical blade angles and number of blades.”

The preceding equation is applicable to a limiting mean radius ratio for the impeller given by the empirical expression

$$\varepsilon = \left(\frac{r_1}{r_2} \right)_{\text{lim}} = \exp \left(\frac{-8.16 \cos \beta'_2}{Z} \right). \quad (7.35c)$$

For values of $r_1/r_2 > \varepsilon$ the following empirical expression is useful:

$$\sigma'_w = \sigma_w \left[1 - \left(\frac{r_1/r_2 - \varepsilon}{1 - \varepsilon} \right)^3 \right]. \quad (7.35d)$$

7.9 HEAD INCREASE OF A CENTRIFUGAL PUMP

The actual delivered head H , measured as the *head difference* between the inlet and outlet flanges of the pump and sometimes called the *manometric head*, is less than the ideal head H_i defined by eqn. (7.4) by the amount of the internal losses. The hydraulic efficiency of the pump is defined as

$$\eta_h = \frac{H}{H_i} = \frac{gH}{U_2 c_{\theta 2}}. \quad (7.36a)$$

From the velocity triangles of Figure 7.5,

$$c_{\theta 2} = U_2 - c_{r2} \tan \beta_2.$$

Therefore,

$$H = \eta_h U_2^2 (1 - \phi_2 \tan \beta_2) / g, \quad (7.36b)$$

where $\phi_2 = c_{r2}/U_2$ and β_2 is the actual averaged relative flow angle at impeller outlet.

With the definition of slip factor, $\sigma = c_{\theta 2}/c'_{\theta 2}$, H can, more usefully, be directly related to the impeller vane outlet angle as

$$H = \eta_h \sigma U_2^2 (1 - \phi_2 \tan \beta'_2) / g. \quad (7.36c)$$

In general, centrifugal pump impellers have between 5 and 12 vanes inclined backwards to the direction of rotation, as suggested in Figure 7.5, with a vane tip angle β'_2 of between 50° and 70° . A knowledge of blade number, β'_2 and ϕ_2 (usually small and on the order of 0.1) generally enables σ to be found using the Busemann formula. The effect of slip, it should be noted, causes the relative flow angle β_2 to become larger than the vane tip angle β'_2 .

Example 7.4

A centrifugal pump delivers $0.1 \text{ m}^3/\text{s}$ of water at a rotational speed of 1200 rev/min. The impeller has seven vanes, which lean backwards to the direction of rotation such that the vane tip angle β'_2 is 50° . The impeller has an external diameter of 0.4 m, an internal diameter of 0.2 m, and an axial width of 31.7 mm. Assuming that the diffuser efficiency is 51.5%, that the impeller head losses are 10% of the ideal head rise, and that the diffuser exit is 0.15 m in diameter, estimate the slip factor, the manometric head and the hydraulic efficiency.

Solution

The criterion given as eqn. (7.35c) is employed *prior* to estimating the slip factor. As $\exp(2\pi \cos \beta'_2/Z) = \exp(2\pi \times 0.643/7) = 1.78$ (which is less than $r_2/r_1 = 2$) then $B = 1$ and $A \approx 0.77$. Note: This value of A is obtained by reploting values of A given in Figure 7.18 for $\beta'_2 = 50^\circ$ and interpolating.

The vane tip speed

$$U_2 = \pi N D_2 / 60 = \pi \times 1200 \times 0.4 / 6 = 25.13 \text{ m/s.}$$

The radial velocity

$$c_{r2} = Q / (\pi D_2 b_2) = 0.1 / (\pi \times 0.4 \times 0.0317) = 2.51 \text{ m/s.}$$

Hence, the Busemann slip factor is

$$\sigma = (0.77 - 0.1 \times 1.192) / (1 - 0.1 \times 1.192) = 0.739.$$

Hydraulic losses occur in the impeller, in the diffuser, and in the volute. The loss in head in the diffuser is

$$\Delta H_D = (p_{02} - p_{03}) / (\rho g) = (p_2 - p_3) / (\rho g) + (c_2^2 - c_3^2) / (2g)$$

and, from eqn. (7.9),

$$p_3 - p_2 = \frac{1}{2} \eta_D \rho (c_2^2 - c_3^2).$$

Substituting in the previous line, we find

$$\Delta H_D = (1 - \eta_D)(c_2^2 - c_3^2) / (2g).$$

The kinetic energy leaving the diffuser is only partly recovered. Watson and Janota (1982) ascribe the total loss in the volute as about *half the dynamic head leaving the diffuser*, and this is also assumed in this calculation. The exit head loss is $0.5 \times c_3^2 / (2g)$ and the head loss in the impeller is $0.1 \times U_2 c_{\theta 2} / g$.

Summing all the losses,

$$H_L = 0.485 \times (c_2^2 - c_3^2) / (2g) + 0.1 \times U_2 c_{\theta 2} / g + 0.5 \times c_3^2 / (2g).$$

Determining the velocities and heads needed,

$$c_{\theta 2} = \sigma U_2 (1 - \phi_2 \tan \beta_2) = 0.739 \times 25.13 \times 0.881 = 16.35 \text{ m/s.}$$

$$H_i = U_2 c_{\theta 2} / g = 25.13 \times 16.35 / 9.81 = 41.8 \text{ m.}$$

$$c_2^2 / (2g) = (16.35^2 + 2.51^2) / 19.62 = 13.96 \text{ m.}$$

$$c_3 = 4Q / (\pi d^2) = 0.4 / (\pi \times 0.15^2) = 5.65 \text{ m/s.}$$

$$c_3^2 / (2g) = 1.63 \text{ m.}$$

Therefore,

$$H_L = 4.18 + 0.485(13.96 - 1.63) + 1.63/2 = 10.98 \text{ m.}$$

The manometric head is

$$H = H_i - H_L = 41.8 - 10.98 = 30.82 \text{ m}$$

and the hydraulic efficiency is

$$\eta_h = H/H_i = 73.7\%.$$

7.10 PERFORMANCE OF CENTRIFUGAL COMPRESSORS

Determining the Pressure Ratio

Consider a centrifugal compressor having zero inlet swirl, compressing a perfect gas. With the usual notation the energy transfer is

$$\Delta W = \dot{W}_c / \dot{m} = h_{02} - h_{01} = U_2 c_{\theta 2}.$$

The overall or total-to-total efficiency η_c is

$$\eta_c = \frac{h_{03ss} - h_{01}}{h_{02} - h_{01}} = \frac{C_p T_{01} (T_{03ss}/T_{01} - 1)}{h_{02} - h_{01}} = C_p T_{01} (T_{03ss}/T_{01} - 1) / (U_2 c_{\theta 2}). \quad (7.37)$$

Now the overall pressure ratio is

$$\frac{p_{03}}{p_{01}} = \left(\frac{T_{03ss}}{T_{01}} \right)^{\gamma/(\gamma-1)}. \quad (7.38)$$

Substituting eqn. (7.37) into eqn. (7.38) and noting that $C_p T_{01} = \gamma R T_{01} / (\gamma - 1) = a_{01}^2 / (\gamma - 1)$, the pressure ratio becomes

$$\frac{p_{03}}{p_{01}} = \left[1 + \frac{(\gamma - 1) \eta_c U_2 c_{r2} \tan \alpha_2}{a_{01}^2} \right]^{\gamma/(\gamma-1)}. \quad (7.39)$$

From the velocity triangle at impeller outlet (Figure 7.4),

$$\phi_2 = c_{r2} / U_2 = (\tan \alpha_2 + \tan \beta_2)^{-1}$$

and, therefore,

$$\frac{p_{03}}{p_{01}} = \left[1 + \frac{(\gamma - 1) \eta_c U_2^2 \tan \alpha_2}{a_{01}^2 (\tan \alpha_2 + \tan \beta_2)} \right]^{\gamma/(\gamma-1)}. \quad (7.40a)$$

This formulation is useful if the flow angles can be specified. Alternatively, and more usefully, as $c_{\theta 2} = \sigma c_{\theta 2'} = \sigma (U_2 - c_{r2} \tan \beta_2')$, then

$$\frac{p_{03}}{p_{01}} = [1 + (\gamma - 1) \eta_c \sigma (1 - \phi_2 \tan \beta_2') M_u^2]^{\gamma/(\gamma-1)}, \quad (7.40b)$$

where $M_u = U_2 / a_{01}$ is now defined as a blade Mach number.

**FIGURE 7.19**

Variation of Pressure Ratio with Blade Speed for a Radial-Bladed Compressor ($\beta'_2 = 0$) at Various Values of Efficiency

It is useful and of interest to calculate the variation of the pressure ratio of a radially vaned ($\beta'_2 = 0$) centrifugal air compressor to show the influence of blade speed and efficiency on the performance. With $\gamma = 1.4$ and $\sigma = 0.9$ (i.e., using the Stanitz slip factor, $\sigma = 1 - 1.98/Z$) and assuming $Z = 20$, the results evaluated are shown in Figure 7.19. It is clear that both the efficiency and the blade speed have a strong effect on the pressure ratio.

In the 1970s the limit on blade speed due to centrifugal stress was about 500 m/s and compressor efficiency seldom exceeded 80%. With a slip factor of 0.9, a radial vaned impeller and an inlet temperature of 288 K, the pressure ratio achieved was barely above 5. More recently quite significant improvements in the performance of centrifugal compressors have been obtained, brought about by the development of computer-aided design and analysis techniques. According to Whitfield and Baines (1990) the techniques employed consist of “a judicious mix of empirical correlations and detailed modelling of the flow physics”! However, it is possible to use these computer packages and arrive at a design solution without any real appreciation of the flow phenomena involved. In *all* compressors the problematic part of the flow process is the *diffusion*; boundary layers are very prone to separate and the flow can become very complicated with separated wakes in the flow and unsteady flow downstream of the impeller. It must be stressed that a *broad understanding of the flow processes within*

a centrifugal compressor is still a vital requirement for the more advanced student and for the further progress of new design methods.

A characteristic of all high performance compressors is that as the design pressure ratio has increased, so the range of mass flow between surge and choking has diminished. In the case of the centrifugal compressor, choking can occur when the Mach number entering the diffuser passages is just in excess of unity. This is a severe problem that is aggravated by any shock-induced separation of the boundary layers on the vanes, which will worsen the problem of flow blockage.

Effect of Backswept Vanes

Came (1978) and Whitfield and Baines (1990) have commented upon the trend of obtaining higher pressure ratios from *single-stage compressors* leading to more highly stressed impellers. The increasing use of backswept vanes and higher blade tip speeds result in higher direct stress in the impeller and bending stress in the non-radial vanes. However, methods of computing the stresses in impellers are available, capable of determining both the direct and the bending stresses caused by the impeller rotation.

The effect of using backswept impeller vanes on the pressure ratio is shown in Figure 7.20 for a range of blade Mach numbers. The use of backswept vanes at a given blade speed causes some loss in pressure ratio. In order to maintain a given pressure ratio it is therefore necessary to increase the design speed, which increases the blade stresses.

FIGURE 7.20

Variation of Pressure Ratio versus Blade Mach Number of a Centrifugal Compressor for Selected Backsweep Angles ($\gamma = 1.4$, $\eta_c = 0.8$, $\sigma = 0.9$, $\phi_2 = 0.375$)

With high blade tip speeds the Mach number of the absolute flow leaving the impeller may exceed unity. As this Mach number can be related to the Mach number at entry to the diffuser vanes, it is of some advantage to be able to calculate the former.

Assuming a perfect gas the Mach number at impeller exit M_2 can be written as

$$M_2^2 = \frac{c_2^2}{a_2^2} = \frac{c_2^2}{T_{01}} \times \frac{T_{01}}{T_2} = \frac{c_2^2}{a_{01}^2} \frac{T_{01}}{T_2}, \quad (7.41)$$

since $a_{01}^2 = \gamma R T_{01}$ and $a_2^2 = \gamma R T_2$.

Referring to the outlet velocity triangle, Figure 7.14 (for the impeller with back swept vanes),

$$c_2^2 = c_{r2}^2 + c_{\theta 2}^2 = c_{r2}^2 + (\sigma c_{\theta 2'})^2,$$

where

$$c_{\theta 2'} = U_2 - c_{r2} \tan \beta_{2'},$$

$$\left(\frac{c_2}{U_2} \right)^2 = \phi_2^2 + \sigma^2 (1 - \phi_2 \tan \beta_{2'})^2. \quad (7.42)$$

Assuming that rothalpy remains constant, eqn. (7.2), gives

$$h_2 = \left(h_1 + \frac{1}{2} w_1^2 - \frac{1}{2} U_1^2 \right) + \frac{1}{2} (U_2^2 - w_2^2) = h_{01} + \frac{1}{2} (U_2^2 - w_2^2),$$

hence,

$$\frac{T_2}{T_{01}} = 1 + \frac{(U_2^2 - w_2^2)}{a_{01}^2/(\gamma - 1)} = 1 + \frac{1}{2} (\gamma - 1) M_u^2 \left(1 - \frac{w_2^2}{U_2^2} \right), \quad (7.43)$$

since $h_{01} = C_p T_{01} = a_{01}^2/(\gamma - 1)$.

From the exit velocity triangle, Figure 7.14,

$$\begin{aligned} w_2^2 &= c_{r2}^2 + (U_2 - c_{\theta 2})^2 = c_{r2}^2 + (U_2 - \sigma c_{\theta 2'})^2 \\ &= c_{r2}^2 + [U_2 - \sigma(U_2 - c_{r2} \tan \beta_{2'})]^2, \end{aligned} \quad (7.44)$$

$$1 - \left(\frac{w_2}{U_2} \right)^2 = 1 - \phi_2^2 - [1 - \sigma(1 - \phi_2 \tan \beta_{2'})]^2. \quad (7.45)$$

Substituting eqns. (7.42), (7.43), and (7.45) into eqn. (7.41), we get

$$M_2^2 = \frac{M_u^2 [\sigma^2 (1 - \phi_2 \tan \beta_{2'})^2 + \phi_2^2]}{1 + \frac{1}{2} (\gamma - 1) M_u^2 \{1 - \phi_2^2 - [1 - \sigma(1 - \phi_2 \tan \beta_{2'})]^2\}}. \quad (7.46a)$$

Although eqn. (7.46a) looks rather complicated at first sight it reduces into an easily managed form when a few constant values are inserted. Assuming the same values we used previously, i.e., $\gamma = 1.4$, $\sigma = 0.9$, $\phi_2 = 0.375$, and $\beta_{2'} = 0^\circ, 15^\circ, 30^\circ$ and 45° , the solution for M_2 simplifies to

$$M_2 = \frac{A M_u}{\sqrt{1 + B M_u^2}}, \quad (7.46b)$$

where the values of A and B are given in Table 7.1, and from which the curves of M_2 against M_u in Figure 7.21 have been calculated.

Whitfield and Baines (1990) *assert* that the two most important aerodynamic parameters at impeller exit are the magnitude and direction of the absolute Mach number M_2 . If M_2 has too high a value, the process of efficient flow deceleration within the diffuser itself is more difficult leading to high friction losses as well as the increased possibility of shock losses. If the flow angle α_2 is large the flow path in the vaneless diffuser will be excessively long resulting in high friction losses and possible stall and flow instability. Several researchers, e.g., Rodgers and Sapiro (1972), have shown that the optimum flow angle is in the range $60^\circ < \alpha_2 < 70^\circ$.

Table 7.1 Values of Constants Used to Evaluate M_2

Constant	β'_2			
	0°	15°	30°	45°
A	0.975	0.8922	0.7986	0.676
B	0.1669	0.1646	0.1545	0.1336

FIGURE 7.21

Variation of Impeller Exit Mach Number versus Blade Mach Number of a Centrifugal Compressor for Selected Backsweep Angles ($\gamma = 1.4$, $\sigma = 0.9$, $\phi_2 = 0.375$)

Backswept vanes give a reduction of the impeller discharge Mach number, M_2 , at any given tip speed. A designer making the change from radial vanes to backswept vanes will incur a reduction in the design pressure ratio if the vane tip speed remains the same. To recover the original pressure ratio the designer needs to *increase* the blade tip speed, which, in turn, increases the discharge Mach number. Fortunately, it turns out that this increase in M_2 is rather less than the reduction obtained by the use of backsweep.

Illustrative Exercise

Consider a centrifugal compressor design that assumes the previous design data (Figures 7.20 and 7.21), together with $\beta'_2 = 0^\circ$ and a blade speed such that $M_u = 1.6$. From Figure 7.20 the pressure ratio at this point is 6.9 and, from Figure 7.21, the value of $M_2 = 1.3$. Choosing an impeller with a backsweep angle, $\beta_{2'} = 30^\circ$, the pressure ratio is 5.0 from Figure 7.20 at the *same value* of M_u . So, to restore the original pressure ratio of 6.9 the blade Mach number must be increased to $M_u = 1.81$. At this new condition a value of $M_2 = 1.178$ is obtained from Figure 7.21, a significant reduction from the original value. Greater values of backsweep may produce even further benefit!

The absolute flow angle can now be found from the exit velocity triangle, Figure 7.14:

$$\tan \alpha_2 = \frac{c_{\theta 2}}{c_{r2}} = \frac{\sigma(U_2 - c_{r2} \tan \beta_{2'})}{c_{r2}} = \sigma \left(\frac{1}{\phi_2} - \tan \beta_{2'} \right).$$

Assuming again the values $\sigma = 0.9$, $\phi_2 = 0.375$, then with $\beta'_2 = 0^\circ$, the value of $\alpha_2 = 67.38^\circ$. Similarly, with $\beta'_2 = 30^\circ$, the value of $\alpha_2 = 62^\circ$, i.e., both values of α_2 are within the prescribed acceptable range.

Kinetic Energy Leaving the Impeller

According to van den Braembussche (1985), “the kinetic energy available at the diffuser inlet easily amounts to more than 50% of the total energy added by the impeller.” Using the foregoing analysis we can determine whether this statement is true or not. If the magnitude of the kinetic energy is so large then the importance of efficiently converting this energy into pressure energy can be appreciated. The conversion of the kinetic energy to pressure energy is considered in the following section on diffusers.

We can define the fraction of the kinetic energy at impeller exit to the specific work input as:

$$f_{KE} = \frac{1}{2} c_2^2 / \Delta W, \quad (7.47)$$

where

$$\begin{aligned} \Delta W &= \sigma U_2^2 \left(1 - \phi_2 \tan \beta'_2 \right) \text{ and } \left(\frac{c_2}{U_2} \right)^2 = \left(\frac{c_2}{a_2} \times \frac{a_2}{a_{01}} \times \frac{a_{01}}{U_2} \right)^2 \\ &= \left(\frac{M_2}{M_u} \right)^2 \left(\frac{a_2}{a_{01}} \times \frac{a_{02}}{a_{01}} \right)^2. \end{aligned} \quad (7.48)$$

Defining the total-to-total efficiency of the impeller as

$$\eta_1 = \frac{h_{02s} - h_{01}}{h_{02} - h_{01}} = \frac{h_{01} \left(\frac{T_{02s}}{T_{01}} - 1 \right)}{h_{02} - h_{01}} = \frac{h_{01} \left(p_R^{(\gamma-1)/\gamma} - 1 \right)}{\Delta W},$$

where p_R is the total-to-total pressure ratio across the impeller, then

$$\left(\frac{a_{02}}{a_{01}}\right)^2 = \frac{T_{02}}{T_{01}} = 1 + \frac{\Delta T_0}{T_{01}} = 1 + \frac{\Delta W}{C_p T_{01}} = 1 + \frac{1}{\eta_1} \left(p_R^{(\gamma-1)/\gamma} - 1\right), \quad (7.49)$$

$$\left(\frac{a_{02}}{a_2}\right)^2 = \frac{T_{02}}{T_2} = 1 + \frac{1}{2}(\gamma - 1)M_2^2. \quad (7.50)$$

Substituting eqns. (7.48), (7.49), and (7.50) into eqn. (7.47) we get

$$f_{KE} = \frac{c_2^2/U_2^2}{2\sigma(1 - \phi_2 \tan \beta'_2)} = \frac{(M_2/M_u)^2 \left[1 + \frac{1}{\eta_1} \left(p_R^{(\gamma-1)/\gamma} - 1\right)\right]}{2\sigma(1 - \phi_2 \tan \beta'_2) \left[1 + \frac{1}{2}(\gamma - 1)M_2^2\right]}. \quad (7.51)$$

Illustrative Exercise

Determine f_{KE} assuming that $\beta'_2 = 0$, $\sigma = 0.9$, $\eta_1 = 0.8$, $p_r = 4$, and $\gamma = 1.4$.

Note: It is very convenient to assume that Figures 7.20 and 7.21 can be used to derive the values of the Mach numbers M_u and M_2 . From Figure 7.20 we get $M_u = 1.3$ and from Figure 7.21, $M_2 = 1.117$. Substituting these results into eqn. (7.51), we get

$$f_{KE} = \frac{1}{2 \times 0.9} \left(\frac{1.117}{1.3}\right)^2 \frac{\left[1 + \frac{1}{0.8} (4^{1/3.5} - 1)\right]}{1 + \frac{1}{5} \times 1.117^2} = 0.5276.$$

This calculation has thus verified the assertion of van den Braembussche (given previously) that the kinetic energy available at diffuser inlet amounts to more than 50% of ΔW .

Calculations of f_{KE} at other pressure ratios and sweepback angles show that its value remains about 0.52 provided that σ and η_1 do not change.

Example 7.5

Air at a stagnation temperature of 22°C enters the impeller of a centrifugal compressor in the axial direction. The rotor, which has 17 radial vanes, rotates at 15,000 rev/min. The stagnation pressure ratio between diffuser outlet and impeller inlet is 4.2 and the overall efficiency (total-to-total) is 83%. Determine the impeller tip radius and power required to drive the compressor when the mass flow rate is 2 kg/s and the mechanical efficiency is 97%. Given that the air density at impeller outlet is 2 kg/m³ and the axial width at entrance to the diffuser is 11 mm, determine the absolute Mach number at that point. Assume that the slip factor $\sigma = 1 - 2/Z$, where Z is the number of vanes. (For air take $\gamma = 1.4$ and $R = 0.287$ kJ/(kg K).)

Solution

From eqn. (7.3) the specific work is

$$\Delta W = h_{02} - h_{01} = U_2 c_{\theta 2},$$

as $c_{\theta 1} = 0$. For a radial impeller, $\beta'_2 = 0$, so $c_{\theta 2} = \sigma U_2$. With eqn. (7.37) and some rearranging:

$$U_2^2 = \frac{C_p T_{01} (p_{03}/p_{02}^{(\gamma-1)/\gamma} - 1)}{\sigma \eta_c},$$

where $p_{03}/p_{01} = 4.2$; $C_p = \gamma R/(\gamma - 1) = 1.005 \text{ kJ/kg K}$, $\sigma_s = 1 - 2/17 = 0.8824$. Therefore,

$$U_2^2 = \frac{1005 \times 295(4.2^{0.286} - 1)}{0.8824 \times 0.83} = 20.5 \times 10^4$$

and $U_2 = 452 \text{ m/s}$.

The rotational speed is $\Omega = 15,000 \times 2\pi/60 = 1570 \text{ rad/s}$ and the impeller tip radius is $r_t = U_2/\Omega = 452/1570 = 0.288 \text{ m}$.

The actual shaft power is obtained from

$$\dot{W}_{\text{act}} = \dot{W}_c/\eta_m = \dot{m}\Delta W/\eta_m = 2 \times 0.8824 \times 452^2/0.97 = 373 \text{ kW}.$$

Although the absolute Mach number at the impeller tip can be obtained almost directly from eqn. (7.46a) it may be instructive instead to find it from its basic definition:

$$M_2 = \frac{c_2}{a_2} = \frac{c_2}{(\gamma RT_2)^{1/2}},$$

where

$$c_2 = (c_{\theta 2}^2 + c_{r2}^2)^{1/2}$$

$$c_{r2} = \dot{m}/(\rho_2 2\pi r_t b_2) = 2/(2 \times 2\pi \times 0.288 \times 0.011) = 50.3 \text{ m/s}$$

$$c_{\theta 2} = \sigma U_2 = 400 \text{ m/s}.$$

Therefore,

$$c_2 = \sqrt{400^2 + 50.3^2} = 402.5 \text{ m/s}.$$

Since

$$h_{02} = h_{01} + \Delta W$$

$$h_2 = h_{01} + \Delta W - \frac{1}{2}c_2^2.$$

Therefore,

$$T_2 = T_{01} + (\Delta W - \frac{1}{2}c_2^2)/C_p = 295 + (18.1 - 8.1)10^4/1005 = 394.5 \text{ K}.$$

Hence,

$$M_2 = \frac{402.5}{\sqrt{402 \times 394.5}} = 1.01.$$

7.11 THE DIFFUSER SYSTEM

Centrifugal compressors and pumps are, in general, fitted with either a vaneless or a vaned diffuser to transform the kinetic energy at the impeller outlet into static pressure. The *volute* or *scroll* is the final component of a centrifugal compressor or pump (Figure 7.22). This is a spiral-shaped channel of

**FIGURE 7.22**

Volute of Centrifugal Compressor or Pump

**FIGURE 7.23**

Two Types of Volute

increasing cross-sectional area whose purpose is to collect the flow from the diffuser (or impeller) and deliver it to the exit pipe. The volute for compressors is almost always of the overhung type, usually the choice is imposed by constraints of space. Figure 7.23 shows two types of volute cross-section.

Vaneless Diffusers

The simplest method of diffusion in a radial flow machine is one where the swirl velocity is reduced by an increase in radius (conservation of angular momentum) and the radial component of velocity is

controlled by the radial flow area. From continuity, since $\dot{m} = \rho A c_r = 2\pi r b \rho c_r$, where b is the width of passage, then the radial velocity c_r at radius r is

$$c_r = \frac{r_2 b_2 \rho_2 c_{r2}}{r b \rho}. \quad (7.52)$$

Assuming the flow is frictionless in the diffuser, the angular momentum is constant and $c_\theta = c_{\theta 2} r_2 / r$. Now the tangential velocity component c_θ is usually very much larger than the radial velocity component c_r ; therefore, the ratio of inlet-to-outlet diffuser velocities c_2/c_3 is approximately r_3/r_2 . Clearly, to obtain useful reductions in velocity, vaneless diffusers must be large. This may not be a disadvantage in industrial applications where weight and size may be of secondary importance compared with the cost of a vaned diffuser. A factor in favour of vaneless diffusers is their wide operating range, vaned diffusers being more sensitive to flow variation because of incidence effects.

For a parallel-walled radial diffuser in incompressible flow, the continuity equation requires that rc_θ is constant. Assuming that rc_θ remains constant, then the absolute flow angle $\alpha_2 = \tan^{-1}(c_\theta/c_r)$ is also constant as the fluid is diffused outwards. Under these conditions the flow follows a *logarithmic spiral*. The relationship between the change in the circumferential angle $\Delta\theta$ and the radius ratio of the flow in the diffuser can be found by considering an element of the flow geometry, shown in Figure 7.24. For an increment in radius dr we have, $r d\theta = dr \tan \alpha_2$. Integrating between stations 2 and 3, gives

$$\Delta\theta = \theta_3 - \theta_2 = \tan \alpha_2 \ln \left(\frac{r_3}{r_2} \right). \quad (7.53)$$

Values of $\Delta\theta$ are shown in Figure 7.25 plotted against r_3/r_2 for several values of α_2 . It can be readily seen that when $\alpha_2 > 70^\circ$, rather long flow paths are implied, friction losses will be greater and the diffuser efficiency will be lower.

Vaned Diffusers

With vaned diffusers the vanes are used to remove the swirl of the fluid at a higher rate than is possible by a simple increase in radius, thereby reducing the length of flow path and diameter. The vaned diffuser is clearly advantageous where small unit size is important.

There is a clearance between the impeller and vane leading edges amounting to about $0.04D_2$ for pumps and between $0.1D_2$ to $0.2D_2$ for compressors. This space constitutes a *vaneless diffuser* and its functions are (i) to reduce the circumferential pressure gradient at the impeller tip, (ii) to smooth out velocity variations between the impeller tip and vanes and, (iii) for compressors, to reduce the Mach number at entry to the vanes. Flow calculations in this space follow the same procedure as for vaneless diffusers.

The flow follows an approximately logarithmic spiral path to the vanes after which it is constrained by the diffuser channels. For rapid diffusion the axis of the channel is straight and tangential to the spiral as shown. The passages are generally designed on the basis of simple channel theory with an equivalent angle of divergence of between 8° and 10° to control separation.

In many applications of the centrifugal compressor, size is important and the outside diameter must be minimised. With a vaned diffuser the channel length can be crucial when considering the final size of the compressor. Clements and Artt (1988) considered this and performed a series of experiments aimed at determining the optimum diffuser channel length to width ratio, L/W . They found that, on the compressor they tested, increasing L/W beyond 3.7 did not produce any improvement in the

**FIGURE 7.24**

Element of Flow in Radial Diffuser

performance, the pressure gradient at that point having reached zero. Another significant result found by them was that the pressure gradient in the diffuser channel when $L/W > 2.13$ was no greater than that which could be obtained in a vaneless diffuser. Hence, removing completely that portion of the diffuser after this point would yield the same pressure recovery as with the full diffuser.

The number of diffuser vanes can also have a direct bearing on the efficiency and surge margin of the compressor. Surge occurs at higher flow rates when vaned diffusers are used than when a simple vaneless diffuser design is adopted. It is better to have fewer diffuser vanes than impeller vanes (about half) in order to achieve a wide range of surge-free flow.

With several adjacent diffuser passages sharing the gas from one impeller passage, the uneven velocity distribution from that passage results in alternate diffuser passages being either starved or choked. This is an unstable situation leading to flow reversal in the passages and to surge of the compressor. When the number of diffuser passages is *less* than the number of impeller passages a more uniform total flow results.

Diffuser Design Calculation

The performance of a conical diffuser has been chosen for this purpose using data presented by Sovran and Klomp (1967). This is shown in Figure 7.26 as contour plots of C_p in terms of the geometry of the

**FIGURE 7.25**

Variation of Flow Path Parameters for Parallel-Walled Radial Diffuser (Incompressible Flow)

diffuser, N/R_1 and the area ratio $A_R (= A_2/A_1)$. Two optimum diffuser lines, useful for design purposes, were added by the authors. The first is the line C_p^* , the locus of points that defines the diffuser area ratio A_R , producing the *maximum pressure recovery* for a prescribed non-dimensional length, N/R_1 . The second is the line C_p^{**} , the locus of points defining the diffuser non-dimensional length, producing the *maximum pressure recovery at a prescribed area ratio*. Note; Compressible flow data was not available and incompressible data has been used.

Example 7.6

Using the performance chart given by Sovran and Klomp (Figure 7.26) determine the efficiency of a conical low speed diffuser to give maximum pressure recovery with a prescribed non-dimensional length of 8.0 and evaluate the included angle of the cone.

Solution

From Figure 7.26 at $N/R = 8.0$ we find $C_p = 0.7$ and $A_g = 2.8$. The efficiency of the diffuser is

$$\eta_D = C_p / C_{p,id},$$

where

$$C_{p,id} = 1 - [1/A_R^2] = 0.872,$$

therefore,

$$\eta_D = 0.802.$$

**FIGURE 7.26**

Performance Chart for Conical Diffusers (Adapted from Sovran and Klomp, 1967)

From the geometric expression given for the diffuser shown in Figure 7.7(b) the included angle is

$$2\theta = 2 \tan^{-1} \left[\frac{R_1}{N} \left(A_R^{\frac{1}{2}} - 1 \right) \right] = 2 \tan^{-1} \left[\frac{1}{8} (\sqrt{2.8} - 1) \right] = 9.6^\circ.$$

Note: This angle may be slightly on the high side and a small modification to the area ratio would seem advisable.

7.12 CHOKING IN A COMPRESSOR STAGE

When the through-flow velocity in a passage reaches the speed of sound at some cross-section, the flow *chokes*. For the stationary inlet passage this means that no further increase in mass flow is possible, either by decreasing the back pressure or by increasing the rotational speed. Now the choking behaviour of rotating passages differs from that of stationary passages, making separate analyses for the inlet, impeller, and diffuser a necessity. For each component a simple, one-dimensional approach is used assuming that all flow processes are adiabatic and that the fluid is a perfect gas.

Inlet

Choking takes place when $c^2 = a^2 = \gamma RT$. Since $h_0 = h + \frac{1}{2}c^2$, $C_p T_0 = C_p T + \frac{1}{2}\gamma RT$, and

$$\frac{T}{T_0} = \left(1 + \frac{\gamma R}{2C_p}\right)^{-1} = \frac{2}{\gamma + 1}. \quad (7.54)$$

Assuming the flow in the inlet is isentropic,

$$\frac{\rho}{\rho_0} = \frac{p}{p_0} \frac{T_0}{T} = \left[1 + \frac{1}{2}(\gamma - 1)M^2\right]^{-1/(\gamma - 1)}$$

and when $c = a$, $M = 1$, so that

$$\frac{\rho}{\rho_0} = \left(\frac{2}{\gamma + 1}\right)^{1/(\gamma - 1)}. \quad (7.55)$$

Substituting eqns. (7.54) and (7.55) into the continuity equation, $\dot{m}/A = \rho c = \rho(\gamma RT)^{1/2}$,

$$\frac{\dot{m}}{A} = \rho_0 a_0 \left(\frac{2}{\gamma + 1}\right)^{(\gamma + 1)/2(\gamma - 1)}. \quad (7.56)$$

Thus, since ρ_0 , a_0 refer to inlet stagnation conditions that remain unchanged, the mass flow rate at choking is constant.

Impeller

In the rotating impeller passages, flow conditions are referred to the factor $I = h + \frac{1}{2}(w^2 - U^2)$, which is constant according to eqn. (7.2). At the impeller inlet and for the special case $c_{\theta 1} = 0$, note that $I_1 = h_1 + \frac{1}{2}c_1^2 = h_{01}$. When choking occurs in the impeller passages the *relative velocity* w equals the speed of sound at some section. Now $w^2 = a^2 = \gamma RT$ and $T_{01} = T + (\gamma RT/2C_p) - (U^2/2C_p)$, therefore,

$$\frac{T}{T_{01}} = \left(\frac{2}{\gamma + 1}\right) \left(1 + \frac{U^2}{2C_p T_{01}}\right). \quad (7.57)$$

Assuming isentropic flow, $\rho/\rho_{01} = (T/T_{01})^{1/(\gamma - 1)}$. Using the continuity equation,

$$\begin{aligned} \frac{\dot{m}}{A} &= \rho_{01} a_{01} \left(\frac{T}{T_{01}}\right)^{(\gamma + 1)/2(\gamma - 1)} = \rho_{01} a_{01} \left[\frac{2}{\gamma + 1} \left(1 + \frac{U^2}{2C_p T_{01}}\right)\right]^{(\gamma + 1)/2(\gamma - 1)} \\ &= \rho_{01} a_{01} \left[\frac{2 + (\gamma - 1)U^2/a_{01}^2}{\gamma + 1}\right]^{(\gamma + 1)/2(\gamma - 1)} \end{aligned} \quad (7.58)$$

If choking occurs in the rotating passages, eqn. (7.58) indicates that the mass flow is dependent on the blade speed. As the speed of rotation is increased the compressor can accept a *greater* mass flow, unless choking occurs in some other component of the compressor. The fact that the choking flow in an impeller can vary, depending on blade speed, may seem at first rather surprising; this analysis gives the *reason* for the variation of the choking limit of a compressor.

Diffuser

The relation for the choking flow, eqn. (7.56) holds for the diffuser passages, it being noted that stagnation conditions now refer to the diffuser and not the inlet. Thus,

$$\frac{\dot{m}}{A_2} = \rho_{02} a_{02} \left(\frac{2}{\gamma + 1} \right)^{(\gamma+1)/2(\gamma-1)} \quad (7.59)$$

Clearly, stagnation conditions at the diffuser inlet are dependent on the impeller process. To find how the choking mass flow limit is affected by blade speed it is necessary to refer back to inlet stagnation conditions.

Assuming a radial bladed impeller of efficiency η_i then,

$$T_{02s} - T_{01} = \eta_i (T_{02} - T_{01}) = \eta_i \sigma U_2^2 / C_p.$$

Hence,

$$p_{02}/p_{01} = (T_{02s}/T_{01})^{\gamma/(\gamma-1)} = [1 + \eta_i \sigma U_2^2 / C_p T_{01}]^{\gamma/(\gamma-1)},$$

therefore,

$$\frac{\dot{m}}{A_2} = \rho_{01} a_{01} \frac{[1 + (\gamma - 1) \eta_i \sigma U_2^2 / a_{01}^2]^{\gamma/(\gamma-1)}}{[1 + (\gamma - 1) \sigma U_2^2 / a_{01}^2]^{1/2}} \left(\frac{2}{\gamma + 1} \right)^{(\gamma+1)/2(\gamma-1)} \quad (7.60)$$

In this analysis it should be noted that the diffuser process has been assumed to be isentropic but the impeller process has been assumed anisentropic. Equation (7.60) indicates that the choking mass flow can be varied by changing the impeller speed of rotation.

Note: The preliminary design of centrifugal compressor for a turbocharger is given in Appendix B.

PROBLEMS

Note: In problems 2 to 6 assume γ and R are 1.4 and 287 J/(kg°C), respectively. In problems 1 to 4 assume the stagnation pressure and stagnation temperature at compressor entry are 101.3 kPa and 288 K, respectively.

1. A cheap radial-vaned centrifugal fan is required to provide a supply of pressurised air to a furnace. The specification requires that the fan produce a total pressure rise equivalent to 7.5 cm of water at a volume flow rate of 0.2 m³/s. The fan impeller is fabricated from 30 thin sheet metal vanes, the ratio of the passage width to circumferential pitch at the impeller exit being specified as 0.5, and the ratio of the radial velocity to blade tip speed as 0.1. Assuming that the overall isentropic efficiency of the fan is 0.75 and that the slip can be estimated from Stanitz's expression, eqn. (7.34b), determine
 - (i) the vane tip speed;
 - (ii) the rotational speed and diameter of the impeller;
 - (iii) the power required to drive the fan if the mechanical efficiency is 0.95;
 - (iv) the specific speed.

For air assume the pressure is 10⁵ Pa and the temperature is 20°C.
2. The air entering the impeller of a centrifugal compressor has an absolute axial velocity of 100 m/s. At rotor exit the relative air angle measured from the radial direction is 26°36', the radial component of velocity is 120 m/s, and the tip speed of the radial vanes is 500 m/s. Determine the power required to drive the compressor when the air flow rate is 2.5 kg/s and the mechanical efficiency is 95%. If the radius ratio of the impeller eye is 0.3, calculate a suitable inlet diameter assuming the inlet flow is incompressible. Determine the overall total pressure ratio of the compressor when the total-to-total efficiency is 80%, assuming the velocity at exit from the diffuser is negligible.
3. A centrifugal compressor has an impeller tip speed of 366 m/s. Determine the absolute Mach number of the flow leaving the radial vanes of the impeller when the radial component of velocity at impeller exit is 30.5 m/s and the slip factor is 0.90. Given that the flow area at impeller exit is 0.1 m² and the total-to-total efficiency of the impeller is 90%, determine the mass flow rate.

4. The eye of a centrifugal compressor has a hub–tip radius ratio of 0.4, a maximum relative flow Mach number of 0.9, and an absolute flow that is uniform and completely axial. Determine the optimum speed of rotation for the condition of maximum mass flow given that the mass flow rate is 4.536 kg/s. Also, determine the outside diameter of the eye and the ratio of axial velocity–blade speed at the eye tip. Figure 7.11 may be used to assist the calculations.

5. An experimental centrifugal compressor is fitted with free-vortex guide vanes to reduce the relative air speed at inlet to the impeller. At the outer radius of the eye, air leaving the guide vanes has a velocity of 91.5 m/s at 20° to the axial direction. Determine the inlet relative Mach number, assuming frictionless flow through the guide vanes, and the impeller total-to-total efficiency. Other details of the compressor and its operating conditions are
 - Impeller entry tip diameter, 0.457 m;
 - Impeller exit tip diameter, 0.762 m;
 - Slip factor, 0.9 Radial blades at impeller exit;
 - Radial component of velocity at impeller exit, 53.4 m/s;
 - Rotational speed of impeller, 11,000 rev/min;
 - Static pressure at impeller exit, 223 kPa (abs).

6. A centrifugal compressor has an impeller with 21 vanes, which are radial at exit, a vaneless diffuser, and no inlet guide vanes. At inlet the stagnation pressure is 100 kPa (abs) and the stagnation temperature is 300 K.
 - (i) Given that the mass flow rate is 2.3 kg/s, the impeller tip speed is 500 m/s and the mechanical efficiency is 96%, determine the driving power on the shaft. Use eqn. (7.34b) for the slip factor.
 - (ii) Determine the total and static pressures at diffuser exit when the velocity at that position is 100 m/s. The total-to-total efficiency is 82%.
 - (iii) The reaction, which may be defined as for an axial flow compressor by eqn. (5.19), is 0.5, the absolute flow speed at impeller entry is 150 m/s, and the diffuser efficiency is 84%. Determine the total and static pressures, absolute Mach number, and radial component of velocity at the impeller exit.
 - (iv) Determine the total-to-total efficiency for the impeller.
 - (v) Estimate the inlet–outlet radius ratio for the diffuser assuming the conservation of angular momentum.
 - (vi) Find a suitable rotational speed for the impeller given an impeller tip width of 6 mm.

7. A centrifugal pump is used to raise water against a static head of 18.0 m. The suction and delivery pipes, both 0.15 m diameter, have, respectively, friction head losses amounting to 2.25 and 7.5 times the dynamic head. The impeller, which rotates at 1450 rev/min, is 0.25 m diameter with eight vanes, radius ratio 0.45, inclined backwards at $\beta'_2 = 60^\circ$. The axial width of the impeller is designed so as to give constant radial velocity at all radii and is 20 mm at impeller exit. Assuming a hydraulic efficiency of 0.82 and an overall efficiency of 0.72, determine
 - (i) the volume flow rate;
 - (ii) the slip factor using Busemann's method;
 - (iii) the impeller vane inlet angle required for zero incidence angle;
 - (iv) the power required to drive the pump.

8. A centrifugal pump delivers $50 \text{ dm}^3/\text{s}$ of water at an impeller speed of 1450 rev/min . The impeller has eight vanes inclined backwards to the direction of rotation with an angle at the tip of $\beta'_2 = 60^\circ$. The diameter of the impeller is twice the diameter of the shroud at inlet and the magnitude of the radial component of velocity at impeller exit is equal to that of the axial component of velocity at the inlet. The impeller entry is designed for the optimum flow condition to resist cavitation [see eqn. (7.20)], has a radius ratio of 0.35 and the blade shape corresponds to a well-tested design giving a cavitation coefficient $\sigma_b = 0.3$. Assuming that the hydraulic efficiency is 70% and the mechanical efficiency is 90%, determine
- (i) the diameter of the inlet;
 - (ii) the net positive suction head;
 - (iii) the impeller slip factor using Wiesner's formula;
 - (iv) the head developed by the pump;
 - (v) the power input.

Also calculate values for slip factor using the equations of Stodola and Busemann, comparing the answers obtained with the result found from Wiesner's equation.

9. (a) Write down the advantages and disadvantages of using free-vortex guide vanes upstream of the impeller of a high pressure ratio centrifugal compressor. What other sorts of guide vanes can be used and how do they compare with free-vortex vanes?
- (b) The inlet of a centrifugal air compressor has a shroud diameter of 0.2 m and a hub diameter of 0.105 m. Free-vortex guide vanes are fitted in the duct upstream of the impeller so that the flow on the shroud at the impeller inlet has a relative Mach number, $M_{1,\text{rel}} = 1.0$, an absolute flow angle of $\alpha_1 = 20^\circ$, and a relative flow angle $\beta_1 = 55^\circ$. At inlet the stagnation conditions are 288 K and 10^5 Pa . Assuming frictionless flow into the inlet, determine
- (i) the rotational speed of the impeller;
 - (ii) the air mass flow.
- (c) At exit from the radially vaned impeller, the vanes have a radius of 0.16 m and a design point slip factor of 0.9. Assuming an impeller efficiency of 0.9, determine
- (i) the shaft power input;
 - (ii) the impeller pressure ratio.
10. Sketch a Mollier diagram showing all the stagnation and static points needed to represent the complete flow process in a diffuser. Derive the following expression for the diffuser efficiency:

$$\eta_D = \frac{T_{2s}/T_1 - 1}{T_2/T_1 - 1}.$$

Air enters a diffuser with an averaged velocity of 360 m/s at a stagnation pressure and temperature of 340 kPa and 420 K and leaves at a stagnation pressure of 300 kPa with an averaged velocity of 120 m/s and a static pressure of 285 kPa. Determine,

- (i) the static pressure and Mach number of the air at inlet;
- (ii) the diffuser efficiency;
- (iii) the Mach number at exit and the overall entropy increase.

Take $\gamma = 1.4$ and $C_p = 287 \text{ J/(kg K)}$.

11. At the inlet to an axial diffuser the velocity of the approaching air is 420 m/s, the stagnation pressure is 300 kPa, and the stagnation temperature is 600 K. At exit the stagnation pressure is 285 kPa and the static pressure 270 kPa. Using compressible flow analysis, determine
 - (i) the static temperature, static pressure, and Mach number at inlet and the diffuser efficiency;
 - (ii) the Mach numbers at exit and entry.

For air take $\gamma = 1.376$ and $R = 287 \text{ J/(kg K)}$.

12. A centrifugal compressor fitted with 21 radial vanes with an outside diameter of 400 cm is designed to operate at a rotational speed of 17,400 rpm. Assuming that the air admitted is at 101.3 kPa and a temperature of 15°C, determine,
 - (i) the absolute Mach number of the flow at the impeller tip given that the radial velocity at that location is 30 m/s;
 - (ii) the stagnation pressure of the air leaving the impeller if the total-to-total efficiency of the impeller is 92%;
 - (iii) the mass flow of air passing through the compressor if the axial width of the passage at impeller exit is 2.0 cm.

Assume the Stanitz expression for the slip factor. Take $C_p = 1005 \text{ J/(kg K)}$ and $\gamma = 1.4$.

13. (a) A model low speed centrifugal compressor (a “blower”) runs at 430 rpm and delivers 10 m³/s of air against a pressure head of 60 mm of water. If the pump efficiency is estimated to be 80%, how much power is required to drive the compressor?
 (b) A geometrically similar compressor is made with a diameter 1.8 times the size of the model and is required to work against a pressure head of 80 mm of water. Determine the operating speed and the power needed to drive the compressor assuming dynamically similar conditions apply.
14. A centrifugal pump is required to deliver 0.09 m³/s of water against a back pressure of 100 kPa. The impeller, which rotates at 1250 rpm, is 0.35 m diameter and has nine vanes swept back at 45°. The axial width of the impeller at its tip is 40 mm. Using Wiesner’s slip correlation [assuming that $r_1/r_2 = \varepsilon$ in eqn. (7.35d)] determine the specific work done by the impeller. If the efficiency of the pump is 70%, calculate the power needed to drive the pump. Calculate the specific speed and specific diameter of the pump and compare your results with the data given in Chapter 2.
15. Atmospheric air enters the intake diffuser of a jet aircraft flying at a Mach number of 0.9 at a constant altitude where the static pressure and temperature are 25 kPa and 220 K, respectively. The entrance area of the intake is 0.5 m² and the area at entry to the compressor is 0.8 m². There is a loss of 10% of the stagnation pressure of the air as it flows to the compressor. Using compressible flow theory and assuming adiabatic flow in the intake, determine the Mach number and velocity of the flow entering the compressor.
16. A prototype centrifugal compressor is to be built with an impeller having 19 vanes backswept at $\beta_2' = 30^\circ$, rotating at 12,000 rpm and delivering air at an outlet pressure of 385 kPa. The total-to-total efficiency of the compressor, based upon previous well-established design data, is estimated

as 0.82. It can be assumed that the radial component of the air leaving the impeller equals 0.2 times the impeller tip speed. The air enters the inlet axially at a stagnation temperature and pressure of 288 K and 100 kPa. Determine

- (i) the impeller tip speed and tip diameter using the Wiesner slip factor;
- (ii) the specific speed of the compressor assuming that the axial velocity at entry is equal to the radial component of velocity at impeller outlet. Comment upon whether the chosen value of the efficiency is appropriate.

How well does the specific speed you have found compare with the values shown in Chapter 2?

17. For the preceding problem determine the size of the compressor eye given that the air flow is 8 kg/s the radius ratio $r_{h1}/r_{s1} = 0.4$. What is the value of the absolute Mach number M_1 ?
18. A radial-vaned centrifugal compressor is designed for a rotational speed of 2400 rpm and requires 1 MW of power to compress the incoming air at a flow rate of 8 kg/s. The air enters the intake axially and the stagnation conditions are 103 kPa and 288 K. Assuming the slip factor is 0.9 and the specific speed

$$N_S = \phi^{0.5} / \psi^{0.75} = 0.7,$$

where $\phi = c_{x1}/U_2$ and $\psi = \Delta W/U_2^2$, determine

- (i) the vane tip speed;
- (ii) the axial velocity at inlet, c_{x1} ;
- (iii) the inlet Mach number, M_1 ;
- (vi) the inlet area.

Radial Flow Gas Turbines

I like work; it fascinates me, I can sit and look at it for hours.

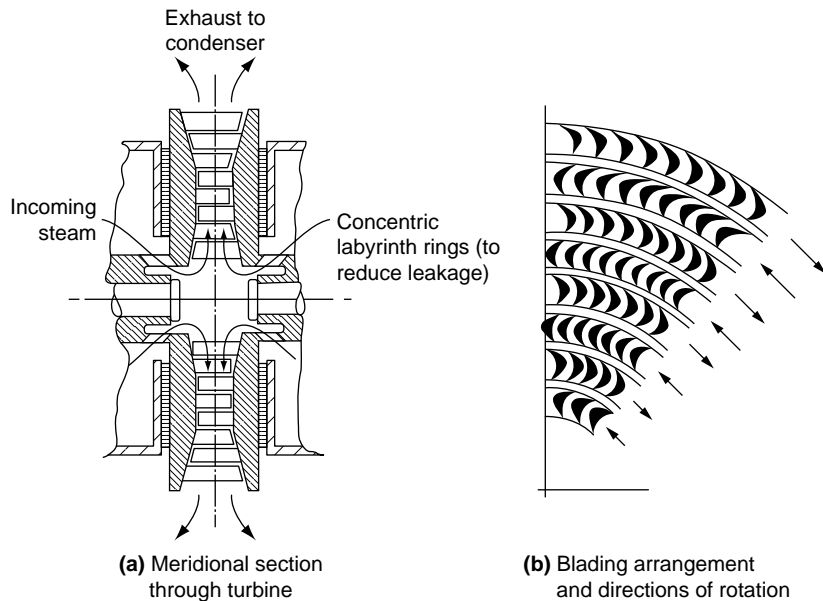

Jerome K. Jerome, *Three Men in a Boat*

8.1 INTRODUCTION

The radial flow turbine has had a long history of development being first conceived for the purpose of producing hydraulic power over 180 years ago. A French engineer, Fourneyron, developed the first commercially successful hydraulic turbine (circa 1830) and this was of the *radial-outflow* type. A *radial-inflow* type of hydraulic turbine was built by Francis and Boyden in the United States (circa 1847), which gave excellent results and was highly regarded. This type of machine is now known as the *Francis turbine*, a simplified arrangement of it being shown in Figure 1.1. It will be observed that the flow path followed is from the radial direction to what is substantially an axial direction. A flow path in the reverse direction (radial outflow), for a single-stage turbine anyway, creates several problems, one of which (discussed later) is low specific work. However, as pointed out by Shepherd (1956) radial-outflow steam turbines comprising many stages have received considerable acceptance in Europe. Figure 8.1 from Kearton (1951) shows diagrammatically the *Ljungström steam turbine*, which, because of the tremendous increase in the specific volume of steam, makes the radial-outflow flow path virtually imperative. A unique feature of the Ljungström turbine is that it does not have any stationary blade rows. The two rows of blades constituting each of the stages rotate in opposite directions so that they can both be regarded as rotors.

The inward-flow radial (IFR) turbine covers tremendous ranges of power, rates of mass flow, and rotational speeds, from very large Francis turbines used in hydroelectric power generation and developing hundreds of megawatts (see Figures 9.12 and 9.13) down to tiny closed cycle gas turbines for space power generation of a few kilowatts.

The IFR gas turbine has been, and continues to be, used extensively for powering automotive turbochargers, aircraft auxiliary power units, expansion units in gas liquefaction, and other cryogenic systems and as a component of the small (10 kW) gas turbines used for space power generation (Anon., 1971). It has been considered for primary power use in automobiles and in helicopters. According to Huntsman, Hudson, and Hill (1992), studies at Rolls-Royce have shown that a cooled, high efficiency IFR turbine could offer significant improvement in performance as the gas generator turbine of a high technology turboshaft engine. What is needed to enable this type of application are some small improvements in current technology levels. However, designers of this new generation

**FIGURE 8.1**

Ljungström Type Outward Flow Radial Turbine (Adapted from Kearton, 1951)

of IFR turbines face considerable problems, particularly in the development of advanced techniques of rotor cooling or of ceramic, shock-resistant rotors.

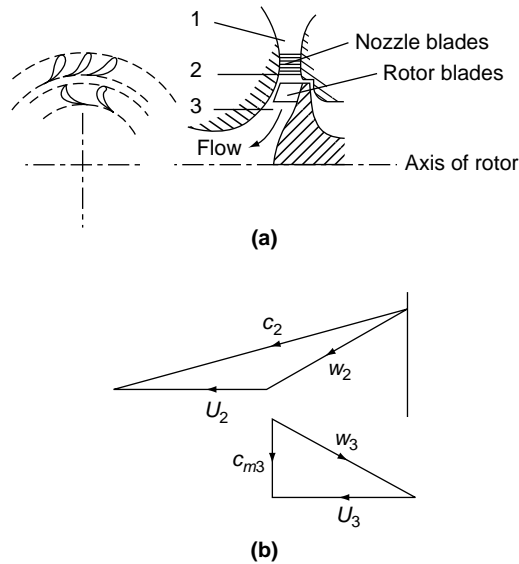

As indicated later in this chapter, over a limited range of specific speed, IFR turbines provide an efficiency about equal to that of the best axial-flow turbines. The significant advantages offered by the IFR turbine compared with the axial-flow turbine is the greater amount of work that can be obtained per stage, the ease of manufacture, and its superior ruggedness.

8.2 TYPES OF INWARD-FLOW RADIAL TURBINE

In the centripetal turbine energy is transferred from the fluid to the rotor in passing from a large radius to a small radius. For the production of positive work the product of Uc_θ at entry to the rotor must be greater than Uc_θ at rotor exit [eqn. (1.18c)]. This is usually arranged by imparting a large component of tangential velocity at rotor entry, using single or multiple nozzles, and allowing little or no swirl in the exit absolute flow.

Cantilever Turbine

Figure 8.2(a) shows a *cantilever* IFR turbine where the blades are limited to the region of the rotor tip, extending from the rotor in the *axial* direction. In practice the cantilever blades are usually of the impulse type (i.e., low reaction), by which it is implied that there is little change in relative velocity

**FIGURE 8.2**

Arrangement of Cantilever Turbine and Velocity Triangles at the Design Point

at inlet and outlet of the rotor. There is no fundamental reason why the blading should not be of the reaction type. However, the resulting expansion through the rotor would require an increase in flow area. This extra flow area is extremely difficult to accommodate in a small radial distance, especially as the radius decreases through the rotor row.

Aerodynamically, the cantilever turbine is similar to an axial-impulse turbine and can even be designed by similar methods. Figure 8.2(b) shows the velocity triangles at rotor inlet and outlet. The fact that the flow is radially inwards hardly alters the design procedure because the blade radius ratio r_2/r_3 is close to unity anyway.

The 90° IFR Turbine

Because of its higher structural strength compared with the cantilever turbine, the 90° IFR turbine is the preferred type. Figure 8.3 shows a typical layout of a 90° IFR turbine; the inlet blade angle is generally made zero, a fact dictated by the material strength and often high gas temperature. The rotor vanes are subject to high stress levels caused by the centrifugal force field, together with a pulsating and often unsteady gas flow at high temperatures. Despite possible performance gains the use of non-radial (or swept) vanes is generally avoided, mainly because of the additional stresses that arise due to bending. Nevertheless, despite this difficulty, Meitner and Glassman (1983) have considered designs using sweptback vanes in assessing ways of increasing the work output of IFR turbines.

From station 2 the rotor vanes extend radially inward and turn the flow into the axial direction. The exit part of the vanes, called the *exducer*, is curved to remove most if not all of the absolute tangential component of velocity. The 90° IFR turbine or centripetal turbine is very similar in appearance to the centrifugal compressor of Chapter 7, but with the flow direction and blade motion reversed.

**FIGURE 8.3**

Layout and Velocity Diagrams for a 90° Inward-Flow Radial Turbine at the Nominal Design Point

The fluid discharging from the turbine rotor may have a considerable velocity c_3 and an axial diffuser (see Chapter 7) would normally be incorporated to recover most of the kinetic energy, $\frac{1}{2}c_3^2$, which would otherwise be wasted. In hydraulic turbines (discussed in Chapter 9) a diffuser is invariably used and is called the *draught tube*.

In Figure 8.3 the velocity triangles are drawn to suggest that the inlet relative velocity, w_2 , is *radially* inward, i.e., zero incidence flow, and the absolute flow at rotor exit, c_3 , is axial. This configuration of the velocity triangles, popular with designers for many years, is called the *nominal design* condition and will be considered in some detail in the following pages. Following this the so-called optimum efficiency design will be explained.

8.3 THERMODYNAMICS OF THE 90° IFR TURBINE

The complete adiabatic expansion process for a turbine comprising a nozzle blade row, a radial rotor followed by a diffuser, corresponding to the layout of Figure 8.3, is represented by the Mollier diagram shown in Figure 8.4. In the turbine, frictional processes cause the entropy to increase in all components and these irreversibilities are implied in Figure 8.4.

Across the nozzle blades the stagnation enthalpy is assumed constant, $h_{01} = h_{02}$ and, therefore, the static enthalpy drop is

$$h_1 - h_2 = \frac{1}{2}(c_2^2 - c_1^2), \quad (8.1)$$

As $h_{01} = h_{02}$,

$$\Delta W = h_{02} - h_{03} = h_2 - h_3 + \frac{1}{2}(c_2^2 - c_3^2) = \frac{1}{2}[(U_2^2 - U_3^2) - (w_2^2 - w_3^2) + (c_2^2 - c_3^2)] \quad (8.4b)$$

after substituting eqn. (8.2a).

8.4 BASIC DESIGN OF THE ROTOR

Each term in eqn. (8.4b) makes a contribution to the specific work done on the rotor. A significant contribution comes from the first term, namely, $\frac{1}{2}(U_2^2 - U_1^2)$, and is the main reason why the inward-flow turbine has such an advantage over the outward-flow turbine where the contribution from this term would be negative. For the axial-flow turbine, where $U_2 = U_1$, of course, no contribution to the specific work is obtained from this term. For the second term in eqn. (8.4b) a positive contribution to the specific work is obtained when $w_3 > w_2$. In fact, accelerating the relative velocity through the rotor is a most useful aim of the designer as this is conducive to achieving a low loss flow. The third term in eqn. (8.4b) indicates that the absolute velocity at rotor inlet should be larger than at rotor outlet so as to increase the work input to the rotor. With these considerations in mind the general shape of the velocity diagram shown in Figure 8.3 results.

Nominal Design

The *nominal design* is defined by a relative flow of zero incidence at rotor inlet (i.e., $w_2 = c_{r2}$) and an absolute flow at rotor exit, which is axial (i.e., $c_3 = c_{x3}$).¹ Thus, from eqn. (8.4a), with $c_{\theta 3} = 0$ and $c_{\theta 2} = U_2$, the specific work for the nominal design is simply

$$\Delta W = U_2^2. \quad (8.4c)$$

Example 8.1

The rotor of an IFR turbine, which is designed to operate at the nominal condition, is 23.76 cm in diameter and rotates at 38,140 rev/min. At the design point the absolute flow angle at rotor entry is 72° . The rotor mean exit diameter is one half of the rotor diameter and the relative velocity at rotor exit is twice the relative velocity at rotor inlet.

Determine the relative contributions to the specific work of each of the three terms in eqn. (8.4b).

Solution

The blade tip speed is $U_2 = \pi ND_2/60 = \pi \times 38,140 \times 0.2376/60 = 474.5$ m/s.

Referring to Figure 8.3, $w_2 = U_2 \cot \alpha_2 = 154.17$ m/s, and $c_2 = U_2/\sin \alpha_2 = 498.9$ m/s.

$$c_3^2 = w_3^2 - U_3^2 = (2 \times 154.17)^2 - \left(\frac{1}{2} \times 474.5\right)^2 = 38,786 \text{ m}^2/\text{s}^2.$$

¹This arrangement ($c_{\theta 3} = 0$) minimizes the exit kinetic energy loss. However, some designers may opt for some exit swirl in the flow in order to benefit a subsequent diffusion process.

Hence,

$$(U_2^2 - U_2^2) = U_2^2(1 - 1/4) = 168,863 \text{ m}^2/\text{s}^2,$$

$$w_3^2 - w_2^2 = 3 \times w_2^2 = 71,305 \text{ m}^2/\text{s}^2$$

and

$$c_2^2 - c_3^2 = 210,115 \text{ m}^2/\text{s}^2.$$

Thus, summing the values of the three terms and dividing by 2, we get $\Delta W = 225,142 \text{ m}^2/\text{s}^2$.

The fractional inputs from each of the three terms are, for the U^2 terms, 0.375; for the w^2 terms, 0.158; for the c^2 terms, 0.467.

Finally, as a numerical check, the specific work is, $\Delta W = U_2^2 = 474.5^2 = 225,150 \text{ m}^2/\text{s}^2$, which, apart from some rounding errors, agrees with the preceding computations. ■

Spouting Velocity

The term *spouting velocity* c_0 (originating from hydraulic turbine practice) is defined as that velocity that has an associated kinetic energy equal to the isentropic enthalpy drop from turbine inlet stagnation pressure p_{01} to the final exhaust pressure. The exhaust pressure here can have several interpretations depending upon whether total or static conditions are used in the related efficiency definition and upon whether or not a diffuser is included with the turbine. Thus, when *no* diffuser is used

$$\frac{1}{2}c_0^2 = h_{01} - h_{03ss} \quad (8.5a)$$

or

$$\frac{1}{2}c_0^2 = h_{01} - h_{3ss} \quad (8.5b)$$

for the total and static cases, respectively.

In an *ideal* (frictionless) radial turbine with complete recovery of the exhaust kinetic energy and with $c_{\theta 2} = U_2$,

$$\Delta W = U_2^2 = \frac{1}{2}c_0^2$$

therefore,

$$\frac{U_2}{c_0} = 0.707.$$

At the best efficiency point of actual (frictional) 90° IFR turbines it is found that this velocity ratio is, generally, in the range $0.68 < U_2/c_0 < 0.71$.

8.5 NOMINAL DESIGN POINT EFFICIENCY

Referring to Figure 8.4, the total-to-static efficiency in the absence of a diffuser is defined as

$$\eta_{ts} = \frac{h_{01} - h_{03}}{h_{01} - h_{3ss}} = \frac{\Delta W}{\Delta W + \frac{1}{2}c_3^2 + (h_3 - h_{3s}) + (h_{3s} - h_{3ss})}. \quad (8.6)$$

The passage enthalpy losses can be expressed as a fraction (ζ) of the exit kinetic energy relative to the nozzle row and the rotor, i.e.,

$$h_3 - h_{3s} = \frac{1}{2}w_3^2\zeta_R, \quad (8.7a)$$

$$h_{3s} - h_{3ss} = \frac{1}{2}c_2^2\zeta_N(T_3/T_2) \quad (8.7b)$$

for the rotor and nozzles, respectively. It is noted that, for a constant pressure process, $ds = dh/T$, hence, the approximation,

$$h_{3s} - h_{3ss} = (h_2 - h_{2s})(T_3/T_2).$$

Substituting for the enthalpy losses in eqn. (8.6),

$$\eta_{ts} = \left[1 + \frac{1}{2}(c_3^2 + w_3^2\zeta_R + c_2^2\zeta_N T_3/T_2)/\Delta W \right]^{-1}. \quad (8.8)$$

From the design point velocity triangles, Figure 8.3,

$$c_2 = U_2 \operatorname{cosec} a_2, \quad w_3 = U_3 \operatorname{cosec} \beta_3, \quad c_3 = U_3 \cot \beta_3, \quad \Delta W = U_2^2.$$

Thus, substituting all these expressions in eqn. (8.8) and noting that $U_3 = U_2 r_3/r_2$,

$$\eta_{ts} = \left\{ 1 + \frac{1}{2} \left[\zeta_N \frac{T_3}{T_2} \operatorname{cosec}^2 a_2 + \left(\frac{r_3}{r_2} \right)^2 (\zeta_R \operatorname{cosec}^2 \beta_3 + \cot^2 \beta_3) \right] \right\}^{-1}, \quad (8.9a)$$

where r_3 and β_3 are taken to apply at the arithmetic mean radius, i.e., $r_3 = \frac{1}{2}(r_{3s} + r_{3h})$. Note that r_{3s} is the shroud radius at rotor exit and r_{3h} is the hub radius at rotor exit. The temperature ratio (T_3/T_2) in eqn. (8.9a) can be obtained as follows.

At the nominal design condition, referring to the velocity triangles of Figure 8.3, $w_3^2 - U_3^2 = c_3^2$, and so eqn. (8.2a) can be rewritten as

$$h_2 - h_3 = \frac{1}{2}(U_2^2 - w_2^2 + c_3^2). \quad (8.2b)$$

This particular relationship, in the form $I = h_{02,rel} - \frac{1}{2}U_2^2 = h_{03}$, can be easily identified in Figure 8.4.

Again, referring to the velocity triangles, $w_2 = U_2 \cot a_2$ and $c_3 = U_3 \cot \beta_3$, a useful alternative form to eqn. (8.2b) is obtained:

$$h_2 - h_3 = \frac{1}{2}U_2^2 [(1 - \cot^2 a_2) + (r_3/r_2) \cot^2 \beta_3], \quad (8.2c)$$

where U_3 is written as $U_2 r_3/r_2$. For a perfect gas the temperature ratio T_3/T_2 can be easily found. Substituting $h = C_p T = \gamma RT/(\gamma - 1)$ in eqn. (8.2c),

$$1 - \frac{T_3}{T_2} = \frac{1}{2} U_2^2 \frac{(\gamma - 1)}{\gamma R T_2} \left[1 - \cot^2 \alpha_2 + \left(\frac{r_3}{r_2} \right)^2 \cot^2 \beta_3 \right],$$

therefore,

$$\frac{T_3}{T_2} = 1 - \frac{1}{2} (\gamma - 1) \left(\frac{U_2}{a_2} \right)^2 \left[1 - \cot^2 \alpha_2 + \left(\frac{r_3}{r_2} \right)^2 \cot^2 \beta_3 \right], \quad (8.2d)$$

where $a_2 = (\gamma R T_2)^{1/2}$ is the sonic velocity at temperature T_2 .

Generally this temperature ratio will have only a very minor effect upon the numerical value of η_{ts} and so it is often ignored in calculations. Thus,

$$\eta_{ts} \simeq \left\{ 1 + \frac{1}{2} \left[\zeta_N \operatorname{cosec}^2 \alpha_2 + \left(\frac{r_3}{r_2} \right)^2 \left(\zeta_R \operatorname{cosec}^2 \beta_3 + \cos^2 \beta_3 \right) \right] \right\}^{-1} \quad (8.9b)$$

is the expression normally used to determine the total-to-static efficiency. An alternative form for η_{ts} can be obtained by rewriting eqn. (8.6) as

$$\eta_{ts} = \frac{h_{01} - h_{03}}{h_{01} - h_{3ss}} = \frac{(h_{01} - h_{3ss}) - (h_{03} - h_3) - (h_3 - h_{3s}) - (h_{3s} - h_{3ss})}{(h_{01} - h_{3ss})} = 1 - (c_3^2 + \zeta_N c_2^2 + \zeta_R w_3^2)/c_0^2, \quad (8.10)$$

where the spouting velocity c_0 is defined by

$$h_{01} - h_{3ss} = \frac{1}{2} c_0^2 = C_p T_{01} \left[1 - (p_3/p_{01})^{(\gamma-1)/\gamma} \right]. \quad (8.11)$$

A simple connection exists between total-to-total and total-to-static efficiency, which can be obtained as follows. Writing

$$\Delta W = \eta_{ts} \Delta W_{is} = \eta_{ts} (h_{01} - h_{3ss})$$

then

$$\eta_{tt} = \frac{\Delta W}{\Delta W_{is} - \frac{1}{2} c_3^2} = \frac{1}{\frac{1}{\eta_{ts}} - \frac{c_3^2}{2 \Delta W}}.$$

Therefore,

$$\frac{1}{\eta_{tt}} = \frac{1}{\eta_{ts}} - \frac{c_3^2}{2 \Delta W} = \frac{1}{\eta_{ts}} - \frac{1}{2} \left(\frac{r_3}{r_2} \cot \beta_3 \right)^2. \quad (8.12)$$

Example 8.2

Performance data from the CAV type 01 radial turbine (Benson, Cartwright, and Das 1968) operating at a pressure ratio p_{01}/p_3 of 1.5 with zero incidence relative flow onto the rotor is presented in the following form:

$$\dot{m}\sqrt{T_{01}/p_{01}} = 1.44 \times 10^{-5}, \quad \text{ms(K)}^{1/2},$$

$$N/\sqrt{T_{01}} = 2410, \quad (\text{rev/min})/\text{K}^{1/2},$$

$$\tau/p_{01} = 4.59 \times 10^{-6}, \quad \text{m}^3,$$

where τ is the torque, corrected for bearing friction loss. The principal dimensions and angles, etc. are given as follows:

- Rotor inlet diameter, 72.5 mm;
- Rotor inlet width, 7.14 mm;
- Rotor mean outlet diameter, 34.4 mm;
- Rotor outlet annulus height, 20.1 mm;
- Rotor inlet angle, 0° ;
- Rotor outlet angle, 53° ;
- Number of rotor blades, 10;
- Nozzle outlet diameter, 74.1 mm;
- Nozzle outlet angle, 80° ;
- Nozzle blade number, 15.

The turbine is “cold tested” with air heated to 400 K (to prevent condensation erosion of the blades). At nozzle outlet an estimate of the flow angle is given as 70° and the corresponding enthalpy loss coefficient is stated to be 0.065. Assuming that the absolute flow at rotor exit is without swirl and uniform and the relative flow leaves the rotor without any deviation, determine the total-to-static and overall efficiencies of the turbine, the rotor enthalpy loss coefficient and the rotor relative velocity ratio.

Solution

The data given are obtained from an actual turbine test and, even though the bearing friction loss has been corrected, there is an additional reduction in the specific work delivered due to disk friction and tip leakage losses, etc. The rotor speed $N = 2410\sqrt{400} = 48,200$ rev/min, the rotor tip speed $U_2 = \pi ND_2/60 = 183$ m/s and, hence, the specific work done by the rotor $\Delta W = U_2^2 = 33.48$ kJ/kg. The corresponding isentropic total-to-static enthalpy drop is

$$h_{01} - h_{3ss} = C_p T_{01} \left[1 - (p_3/p_{01})^{(\gamma-1)/\gamma} \right] = 1.005 \times 400 \left[1 - (1/1.5)^{1/3.5} \right] = 43.97 \text{ kJ/kg}.$$

Thus, the total-to-static efficiency is

$$\eta_{ts} = \Delta W / (h_{01} - h_{3ss}) = 76.14\%.$$

The actual specific work output to the shaft, after allowing for the bearing friction loss, is

$$\begin{aligned} \Delta W_{\text{act}} &= \tau \Omega / \dot{m} = \left(\frac{\tau}{p_{01}} \right) \frac{N}{\sqrt{T_{01}}} \left(\frac{p_{01}}{\dot{m}\sqrt{T_{01}}} \right) \frac{\pi}{30} T_{01} \\ &= 4.59 \times 10^{-6} \times 2410 \times \pi \times 400 / (30 \times 1.44 \times 10^{-5}) \\ &= 32.18 \text{ kJ/kg}. \end{aligned}$$

Thus, the turbine overall total-to-static efficiency is

$$\eta_0 = \Delta W_{\text{act}} / (h_{01} - h_{3ss}) = 73.18\%.$$

By rearranging eqn. (8.9b) the rotor enthalpy loss coefficient can be obtained:

$$\begin{aligned}\zeta_R &= [2(1/\eta_{ts} - 1) - \zeta_N \operatorname{cosec}^2 \alpha_2] (r_2/r_3)^2 \sin^2 \beta_3 - \cos^2 \beta_3 \\ &= [2(1/0.7613 - 1) - 0.065 \times 1.1186] \times 4.442 \times 0.6378 - 0.3622 \\ &= 1.208.\end{aligned}$$

At rotor exit the absolute velocity is uniform and axial. From the velocity triangles, Figure 8.3,

$$w_3^2(r) = U_3^2 + c_3^2 = U_3^2 \left[\left(\frac{r}{r_3} \right)^2 + \cot^2 \beta_3 \right],$$

$$w_2 = U_2 \cot \alpha_2,$$

ignoring blade-to-blade velocity variations. Hence,

$$\frac{w_3(r)}{w_2} = \frac{r_3}{r_2} \tan \alpha_2 \left[\left(\frac{r}{r_3} \right)^2 + \cot^2 \beta_3 \right]^{1/2}. \quad (8.13)$$

The lowest value of this relative velocity ratio occurs when, $r = r_{3h} = (34.4 - 20.1)/2 = 7.15$ mm, so that

$$\frac{w_{3h}}{w_2} = 0.475 \times 2.904 [0.415^2 + 0.7536^2]^{1/2} = 1.19.$$

The relative velocity ratio corresponding to the mean exit radius is

$$\frac{w_3}{w_2} = 0.475 \times 2.904 [1 + 0.7536^2]^{1/2} = 1.73.$$

It is worth commenting that higher total-to-static efficiencies have been obtained in other small radial turbines operating at higher pressure ratios. Rodgers (1969) has suggested that total-to-static efficiencies in excess of 90% for pressure ratios up to 5 to 1 can be attained. Nusbaum and Kofskey (1969) reported an experimental value of 88.8% for a small radial turbine (fitted with an outlet diffuser, admittedly!) at a pressure ratio p_{01}/p_4 of 1.763. In the design point exercise just given the high rotor enthalpy loss coefficient and the corresponding relatively low total-to-static efficiency may well be related to the low relative velocity ratio determined on the hub. Matters are probably worse than this as the calculation is based only on a simple one-dimensional treatment. In determining velocity ratios across the rotor, account should also be taken of the effect of blade-to-blade velocity variation (outlined in this chapter) as well as viscous effects. The number of vanes in the rotor (10) may be insufficient on the basis of Jamieson's theory² (1955), which suggests 18 vanes (i.e., $Z_{\min} = 2\pi \tan \alpha_2$). For this turbine, at lower nozzle exit angles, eqn. (8.13) suggests that the relative velocity ratio becomes even less favourable despite the fact that the Jamieson blade spacing criterion is being approached. (For $Z = 10$, the optimum value of α_2 is about 58° .)

²Included later in this chapter.

8.6 MACH NUMBER RELATIONS

Assuming the fluid is a perfect gas, expressions can be deduced for the important Mach numbers in the turbine. At nozzle outlet the absolute Mach number at the nominal design point is

$$M_2 = \frac{c_2}{a_2} = \frac{U_2}{a_2} \operatorname{cosec} \alpha_2.$$

Now,

$$T_2 = T_{01} - c_2^2 / (2C_p) = T_{01} - \frac{1}{2} U_2^2 \operatorname{cosec}^2 \alpha_2 / C_p.$$

Therefore,

$$\frac{T_2}{T_{01}} = 1 - \frac{1}{2} (\gamma - 1) (U_2 / a_{01})^2 \operatorname{cosec}^2 \alpha_2,$$

where $a_2 = a_{01} (T_2 / T_{01})^{1/2}$. Hence,

$$M_2 = \frac{U_2 / a_{01}}{\sin \alpha_2 \left[1 - \frac{1}{2} (\gamma - 1) (U_2 / a_{01})^2 \operatorname{cosec}^2 \alpha_2 \right]^{1/2}}. \quad (8.14)$$

At rotor outlet the relative Mach number at the design point is defined by

$$M_{3,\text{rel}} = \frac{w_3}{a_3} = \frac{r_3 U_2}{r_2 a_3} \operatorname{cosec} \beta_3.$$

Now,

$$h_3 = h_{01} - \left(U_2^2 + \frac{1}{2} c_3^2 \right) = h_{01} - \left(U_2^2 + \frac{1}{2} U_3^2 \cot^2 \beta_3 \right) = h_{01} - U_2^2 \left[1 + \frac{1}{2} \left(\frac{r_3}{r_2} \cot \beta_3 \right)^2 \right],$$

$$a_3^2 = a_{01}^2 - (\gamma - 1) U_2^2 \left[1 + \frac{1}{2} \left(\frac{r_3}{r_2} \cot \beta_3 \right)^2 \right];$$

therefore,

$$M_{3,\text{rel}} = \frac{(U_2 / a_{01})(r_3 / r_2)}{\sin \beta_3 \left\{ 1 - (\gamma - 1) (U_2 / a_{01})^2 \left[1 + \frac{1}{2} \left(\frac{r_3}{r_2} \cot \beta_3 \right)^2 \right] \right\}^{1/2}}. \quad (8.15)$$

8.7 LOSS COEFFICIENTS IN 90° IFR TURBINES

There are a number of ways of representing the losses in the passages of 90° IFR turbines and these have been listed and inter-related by Benson (1970). As well as the nozzle and rotor passage losses there is a loss at rotor entry at off-design conditions. This occurs when the relative flow entering

the rotor is at some angle of incidence to the radial vanes so that it can be called an *incidence loss*. It is often referred to as *shock loss* but this can be a rather misleading term because, usually, there is no shock wave.

Nozzle Loss Coefficients

The enthalpy loss coefficient, which normally includes the inlet scroll losses, has already been defined and is

$$\zeta_N = (h_2 - h_{2s}) / \left(\frac{1}{2} c_2^2 \right). \quad (8.16)$$

Also in use is the isentropic velocity coefficient,

$$\phi_N = c_2 / c_{2s}, \quad (8.17)$$

and the stagnation pressure loss coefficient,

$$Y_N = (p_{01} - p_{02}) / (p_{02} - p_2), \quad (8.18a)$$

which can be related, approximately, to ζ_N by

$$Y_N \simeq \zeta_N \left(1 + \frac{1}{2} \gamma M_2^2 \right). \quad (8.18b)$$

Since $h_{01} = h_2 + \frac{1}{2} c_2^2 = h_{2s} + \frac{1}{2} c_{2s}^2$, $h_2 - h_{2s} = \frac{1}{2} (c_{2s}^2 - c_2^2)$ and

$$\zeta_N = \frac{1}{\phi_N^2} - 1. \quad (8.19)$$

Practical values of ϕ_N for well-designed nozzle rows in normal operation are usually in the range $0.90 < \phi_N < 0.97$ and $0.23 < \zeta_N < 0.063$.

Rotor Loss Coefficients

At either the design condition (Figure 8.4), or at the off-design condition dealt with later (Figure 8.5), the rotor passage friction losses can be expressed in terms of the following coefficients.

The enthalpy loss coefficient is

$$\zeta_R = (h_3 - h_{3s}) / \left(\frac{1}{2} w_3^2 \right). \quad (8.20)$$

The velocity coefficient is

$$\phi_R = w_3 / w_{3s}, \quad (8.21)$$

which is related to ζ_R by

$$\zeta_R = \frac{1}{\phi_R^2} - 1. \quad (8.22)$$

The normal range of ϕ for well-designed rotors is approximately, $0.70 < \phi_R < 0.85$ and $1.04 < \zeta_R < 0.38$.

**FIGURE 8.5**

Optimum Flow Condition at Inlet to the Rotor: (a) Streamline Flow at Rotor Inlet— p is for Pressure Surface, s is for Suction Surface; (b) Velocity Diagram for the Pitchwise Averaged Flow

8.8 OPTIMUM EFFICIENCY CONSIDERATIONS

According to Abidat et al. (1992) the understanding of incidence effects on the rotors of radial- and mixed-flow turbines is very limited. Normally, IFR turbines are made with radial vanes to reduce bending stresses. In most flow analyses that have been published of the IFR turbine, including all earlier editions of this text, it was assumed that the *average* relative flow at entry to the rotor was radial, i.e., the incidence of the relative flow approaching the radial vanes was zero. The following discussion of the flow model will show that this is an over-simplification and the flow angle for optimum efficiency is significantly different from zero incidence. Rohlik (1975) had asserted that “there is some incidence angle that provides *optimum flow conditions* at the rotor-blade leading edge. This angle has a value sometimes as high as 40° with a radial blade.”

The flow approaching the rotor is assumed to be in the radial plane with a velocity c_2 and flow angle α_2 determined by the geometry of the nozzles or volute. Once the fluid enters the rotor the

process of work extraction proceeds rapidly with reduction in the magnitude of the tangential velocity component and blade speed as the flow radius decreases. Corresponding to these velocity changes is a high blade loading and an accompanying large pressure gradient across the passage from the pressure side to the suction side [Figure 8.5(a)].

With the rotor rotating at angular velocity Ω and the entering flow assumed to be irrotational, a counter-rotating vortex (or relative eddy) is created in the relative flow, whose magnitude is $-\Omega$, which conserves the irrotational state. The effect is virtually the same as that described earlier for the flow leaving the impeller of a centrifugal compressor but in reverse (see Section 7.8 entitled “Slip Factor”). As a result of combining the incoming irrotational flow with the relative eddy, the relative velocity on the pressure (or trailing) surface of the vane is reduced. Similarly, on the suction (or leading) surface of the vane it is seen that the relative velocity is increased. Thus, a static pressure gradient exists *across* the vane passage in agreement with the reasoning of the preceding paragraph.

Figure 8.5(b) indicates the *average* relative velocity w_2 , entering the rotor at angle β_2 and giving optimum flow conditions at the vane leading edge. As the rotor vanes in IFR turbines are assumed to be radial, the angle β_2 is an angle of incidence, and as drawn it is numerically positive. Depending upon the number of rotor vanes this angle may be between 20° and 40° . The static pressure gradient across the passage causes a streamline shift of the flow towards the suction surface. Stream function analyses of this flow condition show that the streamline pattern properly locates the inlet stagnation point on the vane leading edge so that this streamline is approximately radial [see Figure 8.5(a)]. It is reasoned that only at this flow condition will the fluid move smoothly into the rotor passage. Thus, it is the *averaged* relative flow that is at an angle of incidence β_2 to the vane. Whitfield and Baines (1990) have comprehensively reviewed computational methods used in determining turbomachinery flows, including stream function methods.

Wilson and Jansen (1965) appear to have been the first to note that the optimum angle of incidence was virtually identical to the angle of “slip” of the flow leaving the impeller of a radially bladed centrifugal compressor with the same number of vanes as the turbine rotor. Following Whitfield and Baines (1990), an *incidence factor*, λ , is defined, analogous to the slip factor used in centrifugal compressors:

$$\lambda = c_{\theta 2}/U_2.$$

The slip factor most often used in determining the flow angle at rotor inlet is that devised by Stanitz (1952) for radial vaned impellers, so for the incidence factor

$$\lambda = 1 - 0.63\pi/Z \approx 1 - 2/Z. \quad (7.34b)$$

Thus, from the geometry of Figure 8.5(b), we obtain

$$\tan \beta_2 = (2/Z)U_2/c_{m2}. \quad (8.23)$$

To determine the relative flow angle, β_2 , we need to know, at least, the values of the flow coefficient, $\phi_2 = c_{m2}/U_2$ and the vane number Z . A simple method of determining the minimum number of vanes needed in the rotor, due to Jamieson (1955), is given later in this chapter. However, in the next section an optimum efficiency design method devised by Whitfield (1990) provides an alternative way for deriving β_2 .

Design for Optimum Efficiency

Whitfield (1990) presented a general one-dimensional design procedure for the IFR turbine in which, initially, only the required power output is specified. The specific power output is given:

$$\Delta W = \frac{\dot{W}}{\dot{m}} = h_{01} - h_{03} = \frac{\gamma R}{\gamma - 1} (T_{01} - T_{03}) \quad (8.24)$$

and, from this a non-dimensional *power ratio*, S , is defined:

$$S = \Delta W / h_{01} = 1 - T_{03} / T_{01}. \quad (8.25)$$

The power ratio is related to the overall pressure ratio through the total-to-static efficiency:

$$\eta_{ts} = \frac{S}{\left[1 - (p_3/p_{01})^{(\gamma-1)/\gamma} \right]}. \quad (8.26)$$

If the power output, mass flow rate, and inlet stagnation temperature are specified, then S can be directly calculated but, if only the output power is known, then an iterative procedure must be followed.

Whitfield (1990) chose to develop his procedure in terms of the power ratio S and evolved a new non-dimensional design method. At a later stage of the design when the rate of mass flow and inlet stagnation temperature can be quantified, the actual gas velocities and turbine size can be determined. Only the first part of Whitfield's method dealing with the rotor design is considered in this chapter.

Solution of Whitfield's Design Problem

At the design point it is usually assumed that the fluid discharges from the rotor in the axial direction so that with $c_{\theta 3} = 0$, the specific work is

$$\Delta W = U_2 c_{\theta 2}$$

and, combining this with eqns. (8.24) and (8.25), we obtain

$$U_2 c_{\theta 2} / a_{01}^2 = S / (\gamma - 1), \quad (8.27)$$

where $a_{01} = (\gamma R T_{01})^{1/2}$ is the speed of sound corresponding to the temperature T_{01} .

Now, from the velocity triangle at rotor inlet, Figure 8.5(b),

$$U_2 - c_{\theta 2} = c_{m2} \tan \beta_2 = c_{\theta 2} \tan \beta_2 / \tan \alpha_2. \quad (8.28)$$

Multiplying both sides of eqn. (8.28) by $c_{\theta 2} / c_{m2}^2$, we get

$$U_2 c_{\theta 2} / c_{m2}^2 - c_{\theta 2}^2 / c_{m2}^2 - \tan \alpha_2 \tan \beta_2 = 0.$$

But,

$$U_2 c_{\theta 2} / c_{m2}^2 = (U_2 c_{\theta 2} / c_2^2) \sec^2 \alpha_2 = c(1 + \tan^2 \alpha_2),$$

which can be written as a quadratic equation for $\tan \alpha_2$:

$$(c - 1) \tan^2 \alpha_2 - b \tan \alpha_2 + c = 0,$$

where, for economy of writing, $c = U_2 c_{\theta 2} / c_2^2$ and $b = \tan \beta_2$. Solving for $\tan \alpha_2$,

$$\tan \alpha_2 = \left[b \pm \sqrt{b^2 + 4c(1-c)} \right] / 2(c-1). \quad (8.29)$$

For a real solution to exist the radical must be greater than, or equal to, zero; i.e., $b^2 + 4c(1-c) \geq 0$. Taking the zero case and rearranging the terms, another quadratic equation is found, namely,

$$c^2 - c - b^2/4 = 0.$$

Hence, solving for c ,

$$c = \left(1 \pm \sqrt{1 + b^2} \right) / 2 = \frac{1}{2} (1 \pm \sec \beta_2) = U_2 c_{\theta 2} / c_2^2. \quad (8.30)$$

From eqn. (8.29) and then eqn. (8.30), the corresponding solution for $\tan \alpha_2$ is

$$\tan \alpha_2 = b / [2(c-1)] = \tan \beta_2 / (-1 \pm \sec \beta_2).$$

The correct choice between these two solutions will give a value for $\alpha_2 > 0$; thus

$$\tan \alpha_2 = \frac{\sin \beta_2}{1 - \cos \beta_2}. \quad (8.31a)$$

It is easy to see from Table 8.1 that a simple numerical relation exists between these two parameters, namely,

$$\alpha_2 = 90 - \beta_2 / 2. \quad (8.31b)$$

From eqns. (8.27) and (8.30), after some rearranging, a minimum stagnation Mach number at rotor inlet can be found:

$$M_{02}^2 = c_2^2 / a_{01}^2 = \left(\frac{S}{\gamma - 1} \right) \frac{2 \cos \beta_2}{1 + \cos \beta_2} \quad (8.32)$$

and the inlet Mach number can be determined using the equation

$$M_2^2 = \left(\frac{c_2}{a_2} \right)^2 = \frac{M_{02}^2}{1 - \frac{1}{2}(\gamma - 1)M_{02}^2}, \quad (8.33)$$

assuming that $T_{02} = T_{01}$, as the flow through the stator is adiabatic.

Now, from eqn. (8.28)

$$\frac{c_{\theta 2}}{U_2} = \frac{1}{1 + \tan \beta_2 / \tan \alpha_2}.$$

Table 8.1 Variation of α_2 for Several Values of β_2

	Degrees			
β_2	10	20	30	40
α_2	85	80	75	70

After rearranging eqn. (8.31a) to give

$$\tan \beta_2 / \tan \alpha_2 = \sec \beta_2 - 1 \quad (8.34)$$

and, combining these equations with eqn. (8.23),

$$c_{\theta 2} / U_2 = \cos \beta_2 = 1 - 2/Z. \quad (8.35)$$

Equation (8.35) is a direct relationship between the number of rotor blades and the relative flow angle at inlet to the rotor. Also, from eqn. (8.31b),

$$\cos 2\alpha_2 = \cos(180 - \beta_2) = -\cos \beta_2,$$

so that, from the identity $\cos 2\alpha_2 = 2 \cos^2 \alpha_2 - 1$, we get the result

$$\cos^2 \alpha_2 = (1 - \cos \beta_2) / 2 = 1/Z, \quad (8.31c)$$

using also eqn. (8.35).

Example 8.3

An IFR turbine with 12 vanes is required to develop 230 kW from a supply of dry air available at a stagnation temperature of 1050 K and a flow rate of 1 kg/s. Using the optimum efficiency design method and assuming a total-to-static efficiency of 0.81, determine

- (i) the absolute and relative flow angles at rotor inlet;
- (ii) the overall pressure ratio, p_{01}/p_3 ;
- (iii) the rotor tip speed and the inlet absolute Mach number.

Solution

- (i) From the gas tables, e.g., Rogers and Mayhew (1995) or NIST Properties of Fluids Tables, at $T_{01} = 1050$ K, we can find values for $C_p = 1.1502$ kJ/kgK and $\gamma = 1.333$. Using eqn. (8.25),

$$S = \Delta W / (C_p T_{01}) = 230 / (1.15 \times 1050) = 0.2.$$

From Whitfield's eqn. (8.31c),

$$\cos^2 \alpha_2 = 1/Z = 0.083333,$$

therefore, $\alpha_2 = 73.22^\circ$ and, from eqn. (8.31b), $\beta_2 = 2(90 - \alpha_2) = 33.56^\circ$.

- (ii) Rewriting eqn. (8.26),

$$\frac{p_3}{p_{01}} = \left(1 - \frac{S}{\eta_{ts}}\right)^{\gamma/(\gamma-1)} = \left(1 - \frac{0.2}{0.81}\right)^4 = 0.32165,$$

therefore, $p_{01}/p_{003} = 3.109$.

- (iii) Using eqn. (8.32),

$$M_{02}^2 = \left(\frac{S}{\gamma - 1}\right) \frac{2 \cos \beta_2}{1 + \cos \beta_2} = \frac{0.2}{0.333} \times \frac{2 \times 0.8333}{1 + 0.8333} = 0.5460$$

therefore, $M = 0.7389$. Using eqn. (8.33),

$$M_2^2 = \frac{M_{02}^2}{1 - \frac{1}{2}(\gamma - 1)M_{02}^2} = \frac{0.546}{1 - (0.333/2) \times 0.546} = 0.6006$$

and $M_2 = 0.775$. To find the rotor tip speed, substitute eqn. (8.35) into eqn. (8.27) to obtain

$$\left(\frac{U_2^2}{a_{01}^2}\right) \cos \beta_2 = \frac{S}{\gamma - 1},$$

therefore,

$$U_2 = a_{01} \sqrt{\frac{S}{(\gamma - 1) \cos \beta_2}} = 633.8 \sqrt{\frac{0.2}{0.333 \times 0.8333}} = 538.1 \text{ m/s},$$

where

$$a_{01} = \sqrt{\gamma R T_{01}} = \sqrt{1.333 \times 287 \times 1,050} = 633.8 \text{ m/s},$$

and $T_{02} = T_{01}$ is assumed. ■

8.9 CRITERION FOR MINIMUM NUMBER OF BLADES

The following simple analysis of the relative flow in a radially bladed rotor is of considerable interest as it illustrates an important fundamental point concerning blade spacing. From elementary mechanics, the radial and transverse components of acceleration, f_r and f_t , respectively, of a particle moving in a radial plane [Figure 8.6(a)] are

$$f_r = \dot{w} - \Omega^2 r \quad (8.36a)$$

$$f_t = r\dot{\Omega} + 2\Omega w, \quad (8.36b)$$

where w is the radial velocity, $\dot{w} = (dw)/(dt) = w(\partial w)/(\partial r)$ (for steady flow), Ω is the angular velocity and $\dot{\Omega} = d\Omega/dt$ is set equal to zero.

Applying *Newton's second law of motion* to a fluid element (as shown in Figure 6.2) of unit depth, ignoring viscous forces, but putting $c_r = w$, the radial equation of motion is

$$(p + dp)(r + dr)d\theta - prd\theta - pdrd\theta = -f_r dm,$$

where the elementary mass $dm = \rho r d\theta dr$. After simplifying and substituting for f_r from eqn. (8.36a), the following result is obtained,

$$\frac{1}{\rho} \frac{\partial p}{\partial r} + w \frac{\partial w}{\partial r} = \Omega^2 r. \quad (8.37)$$

Integrating eqn. (8.37) with respect to r obtains

$$p/\rho + \frac{1}{2} w^2 - \frac{1}{2} U^2 = \text{constant}, \quad (8.38)$$

which is merely the *inviscid form* of eqn. (8.2a).

**FIGURE 8.6**

Flow Models Used in Analysis of Minimum Number of Blades

The torque transmitted to the rotor by the fluid manifests itself as a pressure difference across each radial vane. Consequently, there must be a pressure gradient in the *tangential direction* in the space between the vanes. Again, consider the element of fluid and apply Newton's second law of motion in the tangential direction:

$$dp \times dr = f_t dm = 2\Omega w(\rho r d\theta dr).$$

Hence,

$$\frac{1}{\rho} \frac{\partial p}{\partial \theta} = 2\Omega r w, \quad (8.39)$$

which establishes the magnitude of the tangential pressure gradient. Differentiating eqn. (8.38) with respect to θ ,

$$\frac{1}{\rho} \frac{\partial p}{\partial \theta} = -w \frac{\partial w}{\partial \theta}. \quad (8.40)$$

Thus, combining eqns. (8.39) and (8.40) gives

$$\frac{\partial w}{\partial \theta} = -2\Omega r. \quad (8.41)$$

This result establishes the important fact that *the radial velocity is not uniform across the passage* as is frequently assumed. As a consequence the radial velocity on one side of a passage is lower than on the other side. Jamieson (1955), who originated this method, conceived the idea of determining the *minimum* number of blades based upon these velocity considerations.

Let the mean radial velocity be \bar{w} and the angular space between two adjacent blades be $\Delta\theta = 2\pi/Z$ where Z is the number of blades. The maximum and minimum radial velocities are, therefore,

$$w_{\max} = \bar{w} + \frac{1}{2}\Delta w = \bar{w} + \Omega r \Delta\theta \quad (8.42a)$$

$$w_{\min} = \bar{w} - \frac{1}{2}\Delta w = \bar{w} - \Omega r \Delta\theta \quad (8.42b)$$

using eqn. (8.41).

Making the reasonable assumption that the radial velocity should not drop below zero [see Figure 8.6(b)], the limiting case occurs at the rotor tip, $r = r_2$ with $w_{\min} = 0$. From eqn. (8.42b) with $U_2 = \Omega r_2$, the minimum number of rotor blades is

$$Z_{\min} = 2\pi U_2 / \bar{w}_2. \quad (8.43a)$$

At the design condition, $U_2 = \bar{w}_2 \tan \alpha_2$, hence,

$$Z_{\min} = 2\pi \tan \alpha_2. \quad (8.43b)$$

Jamieson's result, eqn. (8.43b), is plotted in Figure 8.7 and shows that a large number of rotor vanes are required, especially for high absolute flow angles at rotor inlet. In practice a large number of vanes are not used for several reasons, e.g., excessive flow blockage at rotor exit, a disproportionately large "wetted" surface area causing high friction losses, and the weight and inertia of the rotor become relatively high.

Some experimental tests reported by Hiatt and Johnston (1964) are of interest in connection with the analysis just presented. With a nozzle outlet angle $\alpha_2 = 77^\circ$ and a 12 vane rotor, a total-to-static efficiency $\eta_{ts} = 0.84$ was measured at the optimum velocity ratio U_2/c_0 . For that magnitude of flow angle, eqn. (8.43b) suggests 27 vanes would be required to avoid reverse flow at the rotor tip. However, a second test with the number of vanes increased to 24 produced a gain in efficiency of only 1%. Hiatt and Johnston suggested that the criterion for the optimum number of vanes might not simply be the avoidance of local flow reversal but require a compromise between total pressure losses from this cause and friction losses based upon rotor and blade surface areas.

Glassman (1976) preferred to use an empirical relationship between Z and α_2 , namely,

$$Z = \frac{\pi}{30} (110 - \alpha_2) \tan \alpha_2, \quad (8.44)$$

as he also considered Jamieson's result, eqn. (8.43b), gave too many vanes in the rotor. Glassman's result, which gives far fewer vanes than Jamieson's is plotted in Figure 8.7. Whitfield's result, given in eqn. (8.31c), is not too dissimilar from the result given by Glassman's equation, at least for low vane numbers.

**FIGURE 8.7**

Flow Angle at Rotor Inlet as a Function of the Number of Rotor Vanes

8.10 DESIGN CONSIDERATIONS FOR ROTOR EXIT

Several decisions need to be made regarding the design of the rotor exit. The flow angle β_3 , the meridional velocity to blade tip speed ratio c_{m3}/U_2 , the shroud tip to rotor tip radius ratio r_{3s}/r_2 , and the exit hub to shroud radius ratio $v = r_{3h}/r_{3s}$, all have to be considered. It is assumed that the absolute flow at rotor exit is entirely axial so that the relative velocity can be written

$$w_3^2 = c_{m3}^2 + U_3^2.$$

If values of c_{m3}/U_2 and r_3/r_2 can be chosen, then the exit flow angle variation can be found for all radii. From the rotor exit velocity diagram in Figure 8.3,

$$\cot \beta_3(r) = \frac{c_{m3}}{U_2} \frac{r_2}{r} \quad (8.45)$$

The meridional velocity c_{m3} should be kept small in order to minimise the exhaust energy loss, unless an exhaust diffuser is fitted to the turbine.

Rodgers and Geiser (1987) correlated attainable efficiency levels of IFR turbines against the blade tip speed–spouting velocity ratio, U_2/c_0 , and the axial exit flow coefficient, c_{m3}/U_2 , and their result is shown in Figure 8.8. From this figure it can be seen that peak efficiency values are obtained with velocity ratios close to 0.7 and with values of exit flow coefficient between 0.2 and 0.3.

Rohlik (1968) suggested that the ratio of mean rotor exit radius to rotor inlet radius, r_3/r_2 , should not exceed 0.7 to avoid excessive curvature of the shroud. Also, the exit hub to shroud radius

**FIGURE 8.8**

Correlation of Attainable Efficiency Levels of IFR Turbines against Velocity Ratios (Adapted from Rodgers and Geiser, 1987)

ratio, r_{3h}/r_{3s} , should not be less than 0.4 because of the likelihood of flow blockage caused by closely spaced vanes. Based upon the metal thickness alone it is easily shown that

$$(2\pi r_{3h}/Z) \cos \beta_{3h} > t_{3h},$$

where t_{3h} is the vane thickness at the hub. It is also necessary to allow more than this thickness because of the boundary layers on each vane. Some of the rather limited test data available on the design of the rotor exit comes from Rodgers and Geiser (1987) and concerns the effect of rotor radius ratio and blade solidity on turbine efficiency (see Figure 8.9). It is the relative efficiency variation, η/η_{opt} , that is depicted as a function of the rotor inlet radius–exit *root mean square* radius ratio, $r_2/r_{3\text{rms}}$, for various values of a blade solidity parameter, ZL/D_2 (where L is the length of the blade along the mean meridian). This radius ratio is related to the rotor exit hub to shroud ratio, v , by

$$\frac{r_{3\text{rms}}}{r_2} = \frac{r_{3s}}{r_2} \left(\frac{1 + v^2}{2} \right)^{1/2}.$$

From Figure 8.9, for $r_2/r_{3\text{rms}}$, a value between 1.6 and 1.8 appears to be the optimum.

Rohlik (1968) suggested that the ratio of the relative velocity at the mean exit radius to the inlet relative velocity, w_3/w_2 , should be sufficiently high to assure a low total pressure loss. He gave w_3/w_2 a value of 2.0. The relative velocity at the shroud tip will be greater than that at the mean radius depending upon the radius ratio at rotor exit.

Example 8.4

Given the following data for an IFR turbine,

$$c_{m3}/U_2 = 0.25, v = 0.4, r_{3s}/r_2 = 0.7 \quad \text{and} \quad w_3/w_2 = 2.0,$$

determine the ratio of the relative velocity ratio, w_{3s}/w_2 at the shroud.

**FIGURE 8.9**

Effects of Vane Solidity and Rotor Radius Ratio on the Efficiency Ratio of the IFR Turbine (Adapted from Rodgers and Geiser, 1987)

Solution

As $w_{3s}/c_{m3} = \sec \beta_{3s}$ and $w_3/c_{m3} = \sec \beta_3$,

$$\frac{w_{3s}}{w_3} = \frac{\sec \beta_{3s}}{\sec \beta_3}.$$

$$\frac{r_3}{r_{3s}} = \frac{1}{2} (1 + v) = 0.7 \quad \text{and} \quad \frac{r_3}{r_2} = \frac{r_3}{r_{3s}} \frac{r_{3s}}{r_2} = 0.7 \times 0.7 = 0.49.$$

From eqn. (8.45), the angle at mean radius is given by,

$$\cot \beta_3 = \frac{c_{m3} r_2}{U_2 r_3} = \frac{0.25}{0.49} = 0.5102$$

hence, $\beta_3 = 62.97^\circ$,

$$\cot \beta_{3s} = \frac{c_{m3} r_2}{U_2 r_{3s}} = \frac{0.25}{0.7} = 0.3571$$

hence, $\beta_{3s} = 70.35^\circ$, and, therefore,

$$\frac{w_{3s}}{w_2} = \frac{w_{3s} w_3}{w_3 w_2} = \frac{\sec \beta_{3s}}{\sec \beta_3} \times 2 = \frac{0.4544}{0.3363} \times 2 = 2.702.$$

The relative velocity ratio will increase progressively from the hub to the shroud.

Example 8.5

Using the data and results given in Examples 8.3 and 8.4 together with the additional information that the static pressure at rotor exit is 100 kPa and the nozzle enthalpy loss coefficient, $\zeta_N = 0.06$, determine

- (i) the diameter of the rotor and its speed of rotation;
- (ii) the vane width to diameter ratio, b_2/D_2 at rotor inlet.

Solution

- (i) The rate of mass flow is given by

$$\dot{m} = \rho_3 c_{m3} A_3 = \left(\frac{p_3}{RT_3} \right) \left(\frac{c_{m3}}{U_2} \right) U_2 \pi \left(\frac{r_{3s}}{r_2} \right)^2 (1 - v^2) r_2^2.$$

From eqn. (8.25), $T_{03} = T_{01}(1 - S) = 1050 \times 0.8 = 840 \text{ K}$,

$$T_3 = T_{03} - c_{m3}^2 / (2C_p) = T_{03} - \left(\frac{c_{m3}}{U_2} \right)^2 \frac{U_2^2}{2C_p} = 840 - 0.25^2 \times 5.38.1^2 / (2 \times 1150.2).$$

Hence, $T_3 = 832.1 \text{ K}$.

Substituting values into this mass flow equation,

$$1 = [10^5 / (287 \times 832.1)] \times 0.25 \times 538.1 \times 0.7^2 \times \pi \times (1 - 0.4^2) r_2^2;$$

therefore,

$$r_2^2 = 0.01373 \quad \text{and} \quad r_2 = 0.1172 \text{ m},$$

$$D_2 = \underline{0.2343 \text{ m}}$$

$$\Omega = U_2 / r_2 = 4591.3 \text{ rad/s} \quad (N = \underline{43,843 \text{ rev/min}}).$$

- (ii) The rate of mass flow equation is now written as

$$\dot{m} = \rho_2 c_{m2} A_2, \text{ where } A_2 = 2\pi r_2 b_2 = 4\pi r_2^2 (b_2 / D_2).$$

Solving for the absolute velocity at rotor inlet and its components,

$$c_{\theta 2} = SC_p T_{01} / U_2 = 0.2 \times 1150.2 \times 1050 / 538.1 = 448.9 \text{ m/s},$$

$$c_{m2} = c_{\theta 2} / \tan \alpha_2 = 448.9 / 3.3163 = 135.4 \text{ m/s},$$

$$c_2 = c_{\theta 2} / \sin \alpha_2 = 448.9 / 0.9574 = 468.8 \text{ m/s}.$$

To obtain a value for the static density, ρ_2 , we need to determine T_2 and p_2 :

$$T_2 = T_{02} - c_2^2 / (2C_p) = 1050 - 468.8^2 / (2 \times 1150.2) = 954.5 \text{ K},$$

$$h_{02} - h_2 = \frac{1}{2} c_2^2 \text{ and as } \zeta_N = (h_2 - h_{2s}) / \left(\frac{1}{2} c_2^2 \right), \quad h_{01} - h_{2s} = \frac{1}{2} c_2^2 (1 + \zeta_N), \text{ so}$$

$$\frac{T_{02} - T_{2s}}{T_{02}} = \frac{c_2^2(1 + \zeta_N)}{2C_p T_{02}} = \frac{468.8^2 \times 1.06}{2 \times 1150.2 \times 1050} = 0.096447$$

$$\frac{T_{2s}}{T_{01}} = \left(\frac{p_2}{p_{01}} \right)^{(\gamma-1)/\gamma} = 1 - 0.09645 = 0.90355.$$

Therefore,

$$\frac{p_2}{p_{01}} = \left(\frac{T_{2s}}{T_{01}} \right)^{\gamma/(\gamma-1)} = 0.90355^4 = 0.66652,$$

$$p_2 = 3.109 \times 10^5 \times 0.66652 = 2.0722 \times 10^5 \text{ Pa},$$

$$\frac{b_2}{D_2} = \frac{1}{4\pi} \left(\frac{RT_2}{p_2} \right) \left(\frac{\dot{m}}{c_{m2} r_2^2} \right) = \frac{1}{4 \times \pi} \left(\frac{287 \times 954.5}{2.0722 \times 10^5} \right) \frac{1}{135.4 \times 0.01373} = \underline{0.0566}.$$

Example 8.6

For the IFR turbine described in Example 8.3 and using the data and results in Examples 8.4 and 8.5, deduce a value for the rotor enthalpy loss coefficient, ζ_R , at the optimum efficiency flow condition.

Solution

From eqn. (8.10), solving for ζ_R ,

$$\zeta_R = [(1 - \eta_{ts})c_0^2 - c_3^2 - \zeta_N c_2^2]/w_3^2.$$

We need to find values for c_0 , c_3 , w_3 , and c_2 .

From the data,

$$c_3 = c_{m3} = 0.25 \times 538.1 = 134.5 \text{ m/s}.$$

$$w_3 = 2w_2 = 2c_{m2}/\cos \beta_2 = 2 \times 135.4/\cos 33.560 = 324.97 \text{ m/s}.$$

$$\frac{1}{2} c_0^2 = \Delta W/\eta_{ts} = 230 \times 10^3/0.81 = 283.95 \times 10^3.$$

$$c_2 = 468.8 \text{ m/s}.$$

Therefore,

$$\begin{aligned} \zeta_R &= (2 \times 283.95 \times 10^3 \times 0.19 - 134.5^2 - 0.06 \times 468.8^2)/324.97^2 \\ &= 76,624/105,605 = 0.7256. \end{aligned}$$

8.11 SIGNIFICANCE AND APPLICATION OF SPECIFIC SPEED

The concept of specific speed N_s has already been discussed in Chapter 2 and some applications of it have been made already. Specific speed is extensively used to describe turbomachinery operating requirements in terms of shaft speed, volume flow rate and ideal specific work (alternatively, power developed is used instead of specific work). Originally, specific speed was applied almost exclusively to *incompressible* flow machines as a tool in the selection of the optimum type and size of unit. Its application to units handling *compressible* fluids was somewhat inhibited, due, it would appear, to the fact that volume flow rate changes through the machine, which raised the awkward question of which flow rate should be used in the specific speed definition. According to Balje (1981), the significant volume flow rate that should be used for turbines is that in the rotor exit, Q_3 . This has now been widely adopted by many authorities.

Wood (1963) found it useful to factorise the basic definition of the specific speed equation, eqn. (2.14a), in terms of the geometry and flow conditions within the radial-inflow turbine. Adopting the non-dimensional form of specific speed, to avoid ambiguities,

$$N_s = \frac{NQ_3^{1/2}}{\Delta h_{0s}^{3/4}}, \quad (8.46)$$

where N is in rev/s, Q_3 is in m^3/s , and the isentropic total-to-total enthalpy drop Δh_{0s} (from turbine inlet to exhaust) is in joules per kilogram (i.e., square metres per second squared).

For the 90° IFR turbine, writing $U_2 = \pi ND_2$ and $\Delta h_{0s} = \frac{1}{2}c_0^2$, eqn. (8.46) can be factorised as follows:

$$N_s = \frac{Q_3^{1/2}}{(\frac{1}{2}c_0^2)^{3/4}} \left(\frac{U_2}{\pi D_2} \right) \left(\frac{U_2}{\pi ND_2} \right)^{1/2} = \left(\frac{\sqrt{2}}{\pi} \right)^{3/2} \left(\frac{U_2}{c_0} \right)^{3/2} \left(\frac{Q_3}{ND_2^3} \right)^{1/2}. \quad (8.47a)$$

For the *ideal* 90° IFR turbine and with $c_{02} = U_2$, it was shown earlier that the blade speed to spouting velocity ratio, $U_2/c_0 = \sqrt{2} = 0.707$. Substituting this value into eqn. (8.47a),

$$N_s = 0.18 \left(\frac{Q_3}{ND_2^3} \right)^{1/2}, \quad (\text{rev}) \quad (8.47b)$$

i.e., specific speed is directly proportional to the square root of the volumetric flow coefficient.

To obtain some physical significance from eqns. (8.46) and (8.47b), define a *rotor disc area* $A_d = \pi D_2^2/4$ and assume a uniform axial rotor exit velocity c_3 so that $Q_3 = A_3 c_3$, as

$$N = U_2/(\pi D_2) = \frac{c_0 \sqrt{2}}{2\pi D_2}$$

$$\frac{Q_3}{ND_2^3} = \frac{A_3 c_3 2\pi D_2}{\sqrt{2} c_0 D_2^2} = \frac{A_3 c_3}{A_d c_0} \frac{\pi^2}{2\sqrt{2}}.$$

Hence,

$$N_s = 0.336 \left(\frac{c_3}{c_0} \right)^{1/2} \left(\frac{A_3}{A_d} \right)^{1/2}, \quad (\text{rev}) \quad (8.47c)$$

**FIGURE 8.10**

Specific Speed Function for a 90° Inward Flow Radial Turbine (Adapted from Wood, 1963)

or

$$\Omega_s = 2.11 \left(\frac{c_3}{c_0} \right)^{1/2} \left(\frac{A_3}{A_d} \right)^{1/2}, \quad (\text{rad}) \quad (8.47d)$$

In an early study of IFR turbine design for maximum efficiency, Rohlik (1968) specified that the ratio of the rotor shroud diameter to rotor inlet diameter should be limited to a maximum value of 0.7 to avoid excessive shroud curvature and that the exit hub–shroud tip ratio was limited to a minimum of 0.4 to avoid excess hub blade blockage and loss. Using this as data, an upper limit for A_3/A_d can be found,

$$\frac{A_3}{A_d} = \left(\frac{D_{3s}}{D_2} \right)^2 \left[1 - \left(\frac{D_{3h}}{D_{3s}} \right)^2 \right] = 0.7^2 \times (1 - 0.16) = 0.41.$$

Figure 8.10 shows the relationship between Ω_s , the exhaust energy factor $(c_3/c_0)^2$, and the area ratio A_3/A_d based upon eqn. (8.47d). According to Wood (1963), the limits for the exhaust energy factor in gas turbine practice are $0.04 < (c_3/c_0)^2 < 0.30$, the lower value being apparently a flow stability limit.

The numerical value of specific speed provides a general index of flow capacity relative to work output. Low values of Ω_s are associated with relatively small flow passage areas and high values with relatively large flow passage areas. Specific speed has also been widely used as a general indication of achievable efficiency. Figure 8.11 presents a broad correlation of maximum efficiencies for hydraulic and compressible fluid turbines as functions of specific speed. These efficiencies apply to

**FIGURE 8.11**

Specific Speed–Efficiency Characteristics for Various Turbines (Adapted from Wood, 1963)

favourable design conditions with high values of flow Reynolds number, efficient diffusers and low leakage losses at the blade tips. It is seen that over a limited range of specific speed the best radial-flow turbines match the best axial-flow turbine efficiency, but from $\Omega_s = 0.03$ to 10 no other form of turbine handling compressible fluids can exceed the peak performance capability of the axial turbine.

Over the fairly limited range of specific speed ($0.3 < \Omega_s < 1.0$) that the IFR turbine can produce a high efficiency, it is difficult to find a decisive performance advantage in favour of either the axial-flow turbine or the radial-flow turbine. New methods of fabrication enable the blades of small axial-flow turbines to be cast integrally with the rotor so that both types of turbine can operate at about the same blade tip speed. Wood (1963) compared the relative merits of axial and radial gas turbines at some length. In general, although weight, bulk, and diameter are greater for radial than axial turbines, the differences are not so large and mechanical design compatibility can reverse the difference in a complete gas turbine power plant. The NASA nuclear Brayton cycle space power studies were all made with 90° IFR turbines rather than with axial-flow turbines.

The design problems of a small axial-flow turbine were discussed by Dunham and Panton (1973) who studied the cold performance measurements made on a single-shaft turbine of 13 cm diameter, about the same size as the IFR turbines tested by NASA. Tests had been performed with four rotors to try to determine the effects of aspect ratio, trailing edge thickness, Reynolds number and tip clearance. One turbine build achieved a total-to-total efficiency of 90%, about equal to that of the best IFR turbine. However, because of the much higher outlet velocity, the total-to-static efficiency of the axial turbine gave a less satisfactory value (84%) than the IFR type which could be decisive in some applications. They also confirmed that the axial turbine tip clearance was comparatively large, losing 2% efficiency for every 1% increase in clearance. The tests illustrated one major design problem of a small axial turbine that was the extreme thinness of the blade trailing edges needed to achieve the efficiencies stated.

**FIGURE 8.12**

Calculated Performance of 90° IFR Turbine (Adapted from Rohlik, 1968)

8.12 OPTIMUM DESIGN SELECTION OF 90° IFR TURBINES

Rohlik (1968) has examined analytically the performance of 90° inward-flow radial turbines to determine *optimum* design geometry for various applications as characterised by specific speed. His procedure, which extends an earlier treatment of Wood (1963), was used to determine the design point losses and corresponding efficiencies for various combinations of nozzle exit flow angle α_2 , rotor diameter ratio D_2/D_3 , and rotor blade entry height to exit diameter ratio, b_2/D_3 . The losses taken into account in the calculations are those associated with

- (i) nozzle blade row boundary layers;
- (ii) rotor passage boundary layers;
- (iii) rotor blade tip clearance;
- (iv) disc windage (on the back surface of the rotor);
- (v) kinetic energy loss at exit.

A mean flow path analysis was used and the passage losses were based upon the data of Stewart, Witney, and Wong (1960). The main constraints in the analysis were

- (i) $w_3/w_2 = 2.0$;
- (ii) $c_{\theta 3} = 0$;
- (iii) $\beta_2 = \beta_{2,\text{opt}}$, i.e., zero incidence;
- (iv) $r_{3s}/r_2 = 0.7$;
- (v) $r_{3H}/r_{3s} = 0.4$.

Figure 8.12 shows the variation in total-to-static efficiency with specific speed (Ω_s) for a selection of nozzle exit flow angles, α_2 . For each value of α_2 a hatched area is drawn, inside of which the various

FIGURE 8.13

Distribution of Losses along Envelope of Maximum Total-to-Static Efficiency (Adapted from Rohlik, 1968)

FIGURE 8.14

Sections of Radial Turbines of Maximum Static Efficiency (Adapted from Rohlik, 1968)

diameter ratios are varied. The envelope of maximum η_{ts} is bounded by the constraints $D_{3h}/D_{3s} = 0.4$ in all cases and $D_{3s}/D_2 = 0.7$ for $\Omega_s \geq 0.58$ in these hatched regions. This envelope is the *optimum geometry curve* and has a peak η_{ts} of 0.87 at $\Omega_s = 0.58$ rad. An interesting comparison is made by Rohlik with the experimental results obtained by Kofskey and Wasserbauer (1966) on a single 90° IFR turbine rotor operated with several nozzle blade row configurations. The peak value of η_{ts} from this experimental investigation also turned out to be 0.87 at a slightly higher specific speed, $\Omega_s = 0.64$ rad.

The distribution of losses for optimum geometry over the specific speed range is shown in Figure 8.13. The way the loss distributions change is a result of the changing ratio of flow to specific work. At low Ω_s all friction losses are relatively large because of the high ratios of surface area to flow area. At high Ω_s the high velocities at turbine exit cause the kinetic energy leaving loss to predominate.

Figure 8.14 shows several meridional plane sections at three values of specific speed corresponding to the curve of maximum total-to-static efficiency. The ratio of nozzle exit height–rotor diameter,

**FIGURE 8.15**

Variation in Blade Speed–Spouting Velocity Ratio (U_2/c_0) and Nozzle Blade Height–Rotor Inlet Diameter (b_2/D_2) Corresponding to Maximum Total-to-Static Efficiency with Specific Speed (Adapted from Rohlik, 1968)

b_2/D_2 , is shown in Figure 8.15, the general rise of this ratio with increasing Ω_s , reflecting the increase in nozzle flow area³ accompanying the larger flow rates of higher specific speed. Figure 8.15 also shows the variation of U_2/c_0 with Ω_s along the curve of maximum total-to-static efficiency.

8.13 CLEARANCE AND WINDAGE LOSSES

A clearance gap must exist between the rotor vanes and the shroud. Because of the pressure difference between the pressure and suction surfaces of a vane, a leakage flow occurs through the gap introducing a loss in efficiency of the turbine. The minimum clearance is usually a compromise between manufacturing difficulty and aerodynamic requirements. Often, the minimum clearance is determined by the differential expansion and cooling of components under *transient* operating conditions that can compromise the steady state operating condition. According to Rohlik (1968) the loss in specific work as a result of gap leakage can be determined with the simple proportionality

$$\Delta h_c = \Delta h_0(c/b_m), \quad (8.48)$$

where Δh_0 is the turbine specific work uncorrected for clearance or windage losses and c/b_m is the ratio of the gap to average vane height [i.e., $b_m = \frac{1}{2}(b_2 + b_3)$]. A constant axial and radial gap, $c = 0.25$ mm, was used in the analytical study of Rohlik quoted earlier. According to Rodgers (1969) extensive development on small gas turbines has shown that it is difficult to maintain clearances less than about 0.4 mm. One consequence of this is that as small gas turbines are made progressively smaller the *relative* magnitude of the clearance loss must increase.

³The ratio b_2/D_2 is also affected by the pressure ratio but this has not been shown.

The non-dimensional power loss due to windage on the back of the rotor has been given by Shepherd (1956) in the form

$$\Delta P_w / (\rho_2 \Omega^3 D_2^5) = \text{constant} \times \text{Re}^{-1/5},$$

where Ω is the rotational speed of the rotor and Re is a Reynolds number. Rohlik (1968) used this expression to calculate the loss in specific work due to windage,

$$\Delta h_w = 0.56 \rho_2 D_2^2 (U_2/100)^3 / (\dot{m} \text{Re}), \quad (8.49)$$

where \dot{m} is the total rate of mass flow entering the turbine and the Reynolds number is defined by $\text{Re} = U_2 D_2 / \nu_2$, ν_2 being the kinematic viscosity of the gas corresponding to the static temperature T_2 at nozzle exit.

8.14 COOLED 90° IFR TURBINES

The incentive to use higher temperatures in the basic Brayton gas turbine cycle is well known and arises from a desire to increase cycle efficiency and specific work output. In all gas turbines designed for high efficiency a compromise is necessary between the turbine inlet temperature desired and the temperature that can be tolerated by the turbine materials used. This problem can be minimised by using an auxiliary supply of cooling air to lower the temperature of the highly stressed parts of the turbine exposed to the high temperature gas. Following the successful application of blade cooling techniques to axial flow turbines, methods of cooling small radial gas turbines have been developed.

According to Rodgers (1969) the most practical method of cooling small radial turbines is by film (or veil) cooling, Figure 8.16, where cooling air is impinged on the rotor and vane tips. The main problem with this method of cooling being its relatively low *cooling effectiveness*, defined by

$$\varepsilon = \frac{T_{01} - (T_m + \Delta T_0)}{T_{01} - (T_{0c} + \Delta T_0)}, \quad (8.50)$$

where T_m is the rotor metal temperature,

$$\Delta T_0 = \frac{1}{2} U_2^2 / C_p.$$

Rodgers refers to tests that indicate the possibility of obtaining $\varepsilon = 0.30$ at the rotor tip section with a cooling flow of approximately 10% of the main gas flow. Since the cool and hot streams rapidly mix, effectiveness decreases with distance from the point of impingement. A model study of the heat transfer aspects of film-cooled radial-flow gas turbines is given by Metzger and Mitchell (1966).

PROBLEMS

1. A small inward radial flow gas turbine, comprising a ring of nozzle blades, a radial-vaned rotor and an axial diffuser, operates at the nominal design point with a total-to-total efficiency of 0.90. At turbine entry the stagnation pressure and temperature of the gas is 400 kPa and 1140 K. The flow leaving the turbine is diffused to a pressure of 100 kPa and has negligible final velocity. Given that the flow is just choked at nozzle exit, determine the impeller peripheral speed and the flow outlet angle from the nozzles. For the gas assume $\gamma = 1.333$ and $R = 287 \text{ J/(kg}^\circ\text{C)}$.
2. The mass flow rate of gas through the turbine given in Problem 1 is 3.1 kg/s, the ratio of the rotor axial width–rotor tip radius (b_2/r_2) is 0.1 and the nozzle isentropic velocity ratio (ϕ_2) is 0.96. Assuming that the space between nozzle exit and rotor entry is negligible and ignoring the effects of blade blockage, determine
 - (i) the static pressure and static temperature at nozzle exit;
 - (ii) the rotor tip diameter and rotational speed;
 - (iii) the power transmitted assuming a mechanical efficiency of 93.5%.
3. A radial turbine is proposed as the gas expansion element of a nuclear powered Brayton cycle space power system. The pressure and temperature conditions through the stage at the design point are to be as follows:

Upstream of nozzles, $p_{01} = 699 \text{ kPa}$, $T_{01} = 1145 \text{ K}$;

Nozzle exit, $p_2 = 527.2 \text{ kPa}$, $T_2 = 1029 \text{ K}$;

Rotor exit, $p_3 = 384.7 \text{ kPa}$, $T_3 = 914.5 \text{ K}$; $T_{03} = 924.7 \text{ K}$.

The ratio of rotor exit mean diameter to rotor inlet tip diameter is chosen as 0.49 and the required rotational speed as 24,000 rev/min. Assuming the relative flow at rotor inlet is radial and the absolute flow at rotor exit is axial, determine

- (i) the total-to-static efficiency of the turbine;
- (ii) the rotor diameter;
- (iii) the implied enthalpy loss coefficients for the nozzles and rotor row.

The gas employed in this cycle is a mixture of helium and xenon with a molecular weight of 39.94 and a ratio of specific heats of 5/3. The universal gas constant is $R_0 = 8.314 \text{ kJ/(kg-mol K)}$.

4. A film-cooled radial inflow turbine is to be used in a high performance open Brayton cycle gas turbine. The rotor is made of a material able to withstand a temperature of 1145 K at a tip speed of 600 m/s for short periods of operation. Cooling air is supplied by the compressor that operates at a stagnation pressure ratio of 4 to 1, with an isentropic efficiency of 80%, when air is admitted to the compressor at a stagnation temperature of 288 K. Assuming that the effectiveness of the film cooling is 0.30 and the cooling air temperature at turbine entry is the same as that at compressor exit, determine the maximum permissible gas temperature at entry to the turbine. Take $\gamma = 1.4$ for the air. Take $\gamma = 1.333$ for the gas entering the turbine. Assume $R = 287 \text{ J/(kgK)}$ in both cases.

5. The radial inflow turbine in Problem 3 is designed for a specific speed Ω_s of 0.55 (rad). Determine
- the volume flow rate and the turbine power output;
 - the rotor exit hub and tip diameters;
 - the nozzle exit flow angle and the rotor inlet passage width–diameter ratio, b_2/D_2 .
6. An inward flow radial gas turbine with a rotor diameter of 23.76 cm is designed to operate with a gas mass flow of 1.0 kg/s at a rotational speed of 38,140 rev/min. At the design condition the inlet stagnation pressure and temperature are to be 300 kPa and 727°C. The turbine is to be “cold” tested in a laboratory where an air supply is available only at the stagnation conditions of 200 kPa and 102°C.
- Assuming dynamically similar conditions between those of the laboratory and the projected design determine, for the “cold” test, the equivalent mass flow rate and the speed of rotation. Assume the gas properties are the same as for air.
 - Using property tables for air, determine the Reynolds numbers for both the hot and cold running conditions. The Reynolds number is defined in this context as

$$\text{Re} = \rho_{01}ND^2/\mu_{01},$$

where ρ_{01} and μ_{01} are the stagnation density and stagnation viscosity of the air, N is the rotational speed (rev/s), and D is the rotor diameter.

7. For the radial flow turbine described in the previous problem and operating at the prescribed “hot” design point condition, the gas leaves the exducer directly to the atmosphere at a pressure of 100 kPa and without swirl. The absolute flow angle at rotor inlet is 72° to the radial direction. The relative velocity w_3 at the mean radius of the exducer (which is one half of the rotor inlet radius r_2) is twice the rotor inlet relative velocity w_2 . The nozzle enthalpy loss coefficient, $\zeta_N = 0.06$. Assuming the gas has the properties of air with an average value of $\gamma = 1.34$ (this temperature range) and $R = 287$ J/kg K, determine
- the total-to-static efficiency of the turbine;
 - the static temperature and pressure at the rotor inlet;
 - the axial width of the passage at inlet to the rotor;
 - the absolute velocity of the flow at exit from the exducer;
 - the rotor enthalpy loss coefficient;
 - the radii of the exducer exit given that the radius ratio at that location is 0.4.
8. One of the early space power systems built and tested for NASA was based on the Brayton cycle and incorporated an IFR turbine as the gas expander. Some of the data available concerning the turbine are as follows:

Total-to-total pressure ratio (turbine inlet to turbine exit), $p_{01}/p_{03} = 1.560$;

Total-to-static pressure ratio, $p_{01}/p_3 = 1.613$;

Total temperature at turbine entry, $T_{01} = 1083$ K;

Total pressure at inlet to turbine, $T_{01} = 91$ kPa;

Shaft power output (measured on a dynamometer), $P_{\text{net}} = 22.03$ kW;

Bearing and seal friction torque (a separate test), $\tau_f = 0.0794$ Nm;

Rotor diameter, $D_2 = 15.29$ cm;
 Absolute flow angle at rotor inlet, $\alpha_2 = 72^\circ$;
 Absolute flow angle at rotor exit, $\alpha_3 = 0^\circ$;
 The hub to shroud radius ratio at rotor exit, $r_{3h}/r_{3s} = 0.35$;
 Ratio of blade speed to jet speed, $v = U_2/c_0 = 0.6958$;
 (c_0 based on total-to-static pressure ratio.)

For reasons of crew safety, an inert gas argon ($R = 208.2$ J/(kg K), ratio of specific heats, $\gamma = 1.667$) was used in the cycle. The turbine design scheme was based on the concept of optimum efficiency. Determine, for the design point

- (i) the rotor vane tip speed;
- (ii) the static pressure and temperature at rotor exit;
- (iii) the gas exit velocity and mass flow rate;
- (iv) the shroud radius at rotor exit;
- (v) the relative flow angle at rotor inlet;
- (vi) the specific speed.

Note: The volume flow rate to be used in the definition of the specific speed is based on the rotor exit conditions.

9. What is meant by the term *nominal design* in connection with a radial flow gas turbine rotor? Sketch the velocity diagrams for a 90° IFR turbine operating at the nominal design point. At entry to a 90° IFR turbine the gas leaves the nozzle vanes at an absolute flow angle, α_2 , of 73° . The rotor blade tip speed is 460 m/s and the relative velocity of the gas at rotor exit is twice the relative velocity at rotor inlet. The rotor mean exit diameter is 45% of the rotor inlet diameter. Determine,

- (i) the exit velocity from the rotor;
- (ii) the static temperature difference, $T_2 - T_3$, of the flow between nozzle exit and rotor exit.

Assume the turbine operates at the nominal design condition and that $C_p = 1.33$ kJ/kg K.

10. The initial design of an IFR turbine is to be based upon Whitfield's procedure for optimum efficiency. The turbine is to be supplied with 2.2 kg/s of air, a stagnation pressure of 250 kPa, a stagnation temperature of 800°C , and have an output power of 450 kW. At turbine exit the static pressure is 105 kPa. Assuming for air that $\gamma = 1.33$ and $R = 287$ J/kg K, determine the value of Whitfield's power ratio, S , and the total-to-static efficiency of the turbine.
11. By considering the theoretical details of Whitfield's design problem for obtaining the optimum efficiency of an IFR turbine show that the correct choice for the relationship of the rotor inlet flow angles is obtained from the following equation,

$$\tan \alpha_2 = \frac{\sin \beta_2}{1 - \cos \beta_2}.$$

and that a minimum stagnation Mach number at rotor inlet is obtained from:

$$M_{02}^2 = \left(\frac{S}{\gamma - 1} \right) \frac{2 \cos \beta_2}{1 + \cos \beta_2}.$$

12. An IFR turbine rotor is designed with 13 vanes and is expected to produce 400 kW from a supply of gas heated to a stagnation temperature of 1100 K at a flow rate of 1.2 kg/s. Using Whitfield's optimum efficiency design method and assuming $\eta_{ts} = 0.85$, determine
- the overall stagnation pressure to static pressure ratio;
 - the rotor tip speed and inlet Mach number, M_2 , of the flow.

Assume $C_p = 1.187$ kJ/kg K and $\gamma = 1.33$.

13. Another IFR turbine is to be built to develop 250 kW of shaft power from a gas flow of 1.1 kg/s. The inlet stagnation temperature, T_{01} , is 1050 K, the number of rotor blades is 13, and the outlet static pressure, p_3 , is 102 kPa. At rotor exit the area ratio, $v = r_{3h}/r_{3s} = 0.4$, and the velocity ratio, $c_{m3}/U_2 = 0.25$. The shroud to rotor inlet radius, r_{3s}/r_2 , is 0.4. Using the optimum efficiency design method, determine
- the power ratio, S , and the relative and absolute flow angles at rotor inlet;
 - the rotor blade tip speed;
 - the static temperature at rotor exit;
 - the rotor speed of rotation and rotor diameter.

Evaluate the specific speed, Ω_s . How does this value compare with the optimum value of specific speed determined in Figure 8.15?

14. Using the same input design data for the IFR turbine given in Problem 5 and given that the total-to-static efficiency is 0.8, determine
- the stagnation pressure of the gas at inlet;
 - the total-to-total efficiency of the turbine.
15. An IFR turbine is required with a power output of 300 kW driven by a supply of gas at a stagnation pressure of 222 kPa, at a stagnation temperature of 1100 K, and at a flow rate of 1.5 kg/s. The turbine selected by the engineer has 13 vanes and preliminary tests indicate it should have a total-to-static efficiency of 0.86. Based upon the optimum efficiency design method sketch the appropriate velocity diagrams for the turbine and determine
- the absolute and relative flow angles at rotor inlet;
 - the overall pressure ratio;
 - the rotor tip speed.

16. For the IFR turbine of the previous problem the following additional information is made available:

$$c_{m3}/U_2 = 0.25, w_3/w_2 = 2.0, r_{3s}/r_2 = 0.7 \text{ and } v = 0.4.$$

Again, based upon the optimum efficiency design criterion, determine,

- the rotor diameter and speed of rotation;
- the enthalpy loss coefficients of the rotor and the nozzles given that the nozzle loss coefficient is (estimated) to be one quarter of the rotor loss coefficient.

Hydraulic Turbines

9

Hear ye not the hum of mighty workings?

John Keats, Sonnet No. 14

The power of water has changed more in this world than emperors or kings.

Leonardo da Vinci

9.1 INTRODUCTION

To put this chapter into perspective some idea of the scale of hydropower development in the world might be useful before delving into the intricacies of hydraulic turbines. A very detailed and authoritative account of virtually every aspect of hydropower is given by Raabe (1985) and this brief introduction serves merely to illustrate a few aspects of a very extensive subject.

Hydropower is the longest established source for the generation of electric power, which, starting in 1880 as a small dc generating plant in Wisconsin, United States, developed into an industrial size plant following the demonstration of the economic transmission of high voltage ac at the Frankfurt Exhibition in 1891. Hydropower was expected to have a worldwide yearly growth rate of about 5% (i.e., doubling in size every 15 years) but this rate has now proved to be too optimistic. In 1980 the worldwide installed generating capacity was 460 GW according to the United Nations (1981) but in 2007 the figure was just exceeding 700 GW. This works out at roughly 1.6% annual yearly growth. The smaller growth rate must, primarily, be due to the high costs involved in the civil engineering work, the cost of the power and related electrical plant, and to some extent the human cost due to massive population displacements with necessary new building.

According to the Environmental Resources Group Ltd., in 2007 hydropower constituted about 21% of the world's electrical generating capacity. The theoretical potential of hydropower is believed to be 2800 GW. The main areas with potential for growth are China, Latin America, and Africa.

Table 9.1 is an extract of data quoted by Raabe (1985) of the distribution of harnessed and harnessable potential of some of the countries with the biggest usable potential of hydropower. From this list it is seen that the People's Republic of China (PRC), the country with the largest harnessable potential in the world had, in 1974, harnessed only 4.22% of this. However, the Three Gorges Dam project on the Yangtse River, is now the biggest hydropower plant in the world. It contains 32 Francis turbines

Table 9.1 Distribution of Harnesses and Harnessable Potential of Hydroelectric Power

Country	Usable Potential, TWh	Amount of Potential Used, TWh	Percentage of Usable Potential
1 China (PRC)	1320	55.6	4.22
2 Former USSR	1095	180	16.45
3 USA	701.5	277.7	39.6
4 Zaire	660	4.3	0.65
5 Canada	535.2	251	46.9
6 Brazil	519.3	126.9	24.45
7 Malaysia	320	1.25	0.39
8 Columbia	300	13.8	4.6
9 India	280	46.87	16.7
Sum 1–9	5731	907.4	15.83
Other countries	4071	843	20.7
Total	9802.4	1750.5	17.8

each capable of generating 700 MW, and in 2011, when all of the plant is fully operational, the total generating capacity will be 22,500 MW.

Tidal Power

This relatively new and very promising technology, in which tidal stream generators are used to generate power, is still under active development. Very large amounts of energy can be obtained by this means and, unlike wind power and solar power, it is available at known times each day. The most efficient type of generator is still to be determined. The world's first commercial tidal stream generator, *SeaGen*, was installed in 2008 at Strangford Lough, Northern Ireland. The prototype version comprises two 600 kW axial-flow turbines, 16 m in diameter. Further details on this tidal turbine are given towards the end of this chapter.

Wave Power

Several energy conversion systems have now been developed for obtaining electrical power from sea waves. One notable example is the *Wells turbine*, which uses an oscillating water column generated by the waves to drive this special type of axial-flow turbine. Several of these turbines have been installed (in Scotland and India) and details of their rather special fluid mechanical design are given in this chapter.

Features of Hydropower Plants

The initial cost of hydropower plants may be much higher than those of thermal power plants. However, the present value of total costs (which includes those of fuel) is, in general, lower in hydropower plants. Raabe (1985) listed the various advantages and disadvantages of hydropower plants and a brief summary of these is given in Table 9.2.

Table 9.2 Features of Hydroelectric Power Plants

Advantages	Disadvantages
Technology is relatively simple and proven. High efficiency. Long useful life. No thermal phenomena apart from those in bearings and generator.	Number of favourable sites limited and available only in some countries. Problems with cavitation and water hammer.
Small operating, maintenance, and replacement costs.	High initial cost especially for low head plants compared with thermal power plants.
No air pollution. No thermal pollution of water.	Inundation of the reservoirs and displacement of the population. Loss of arable land. Facilitates sedimentation upstream and erosion downstream of a barrage.

9.2 HYDRAULIC TURBINES

Early History of Hydraulic Turbines

The hydraulic turbine has a long period of development, its oldest and simplest form being the waterwheel, first used in ancient Greece and subsequently adopted throughout medieval Europe for the grinding of grain, etc. A French engineer, Benoit Fourneyron, developed the first commercially successful hydraulic turbine (circa 1830). Later Fourneyron built turbines for industrial purposes that achieved a speed of 2300 rev/min, developing about 50 kW at an efficiency of over 80%.

The American engineer James B. Francis designed the first *radial-inflow* hydraulic turbine that became widely used, gave excellent results, and was highly regarded. In its original form it was used for heads of between 10 and 100 m. A simplified form of this turbine is shown in Figure 1.1(d) in Chapter 1. It will be observed that the flow path followed is essentially from a radial direction to an axial direction.

The Pelton wheel turbine, named after its American inventor, Lester A. Pelton, was brought into use in the second half of the nineteenth century. This is an impulse turbine in which water is piped at high pressure to a nozzle where it expands completely to atmospheric pressure. The emerging jet impacts onto the blades (or buckets) of the turbine, which produce the required torque and power output. A simplified diagram of a Pelton wheel turbine is shown in Figure 1.1(f). The head of water used originally was between about 90 and 900 m (modern versions operate up to heads of nearly 2000 m).

The increasing need for more power during the early years of the twentieth century also led to the invention of a turbine suitable for small heads of water, i.e., 3 to 9 m, in river locations where a dam could be built. In 1913 Viktor Kaplan revealed his idea of the propeller (or Kaplan) turbine, see Figure 1.1(e), which acts like a ship's propeller but in reverse. At a later date Kaplan improved his turbine by means of swiveling blades, which improved the efficiency of the turbine appropriate to the available flow rate and head.

Flow Regimes for Maximum Efficiency

The efficiency of a hydraulic turbine can be defined as the work developed by the rotor in unit time divided by the difference in hydraulic energy between inlet and outlet of the turbine in unit time. The

efficiencies of the three principal types of hydraulic turbine just mentioned are shown in Figure 9.1 as functions of the power specific speed, Ω_{sp} . From eqn. (2.15b), this is

$$\Omega_{sp} = \frac{\Omega \sqrt{P/\rho}}{(gH_E)^{3/4}}, \quad (9.1)$$

where P is the power delivered by the shaft, ρ is the density of water, H_E is the effective head at turbine entry, and Ω is the rotational speed in radians per second. It is remarkable that the efficiency of the multi-stage Pelton turbine has now reached 92.5% at $\Omega_{sp} \cong 0.2$ and that the Francis turbine can achieve an efficiency of 95 to 96% at an $\Omega_{sp} \cong 1.0$ to 2.0.

The Ω_{sp} regimes of these turbine types are of considerable importance to the designer as they indicate the most suitable choice of machine for an application. In general, low specific speed machines correspond to low volume flow rates and high heads, whereas high specific speed machines correspond to high volume flow rates and low heads. Table 9.3 summarises the normal operating ranges for the specific speed, the effective head, the maximum power and best efficiency for each type of turbine.

FIGURE 9.1

Typical Design Point Efficiencies of Pelton, Francis, and Kaplan Turbines

Table 9.3 Operating Ranges of Hydraulic Turbines

	Pelton Turbine	Francis Turbine	Kaplan Turbine
Specific speed (rad)	0.05–0.4	0.4–2.2	1.8–5.0
Head (m)	100–1770	20–900	6–70
Maximum power (MW)	500	800	300
Optimum efficiency (%)	90	95	94
Regulation method	Needle valve and deflector plate	Stagger angle of guide vanes	Stagger angle of rotor blades

Note: Values shown in the table are only a rough guide and are subject to change.

**FIGURE 9.2**

Application Ranges for Various Types of Hydraulic Turbomachines, as a plot of Q versus H with Lines of Constant Power Determined Assuming $\eta_0 = 0.8$ (Courtesy Sulzer Hydro Ltd., Zurich)

According to the experience of Sulzer Hydro Ltd., of Zurich, the application ranges of the various types of turbines and turbine pumps (including some not mentioned here) are plotted in Figure 9.2 on a $\ln Q$ versus $\ln H_E$ diagram and reflect the present state of the art of hydraulic turbomachinery design. Also in Figure 9.2 lines of constant power output are conveniently shown and have been calculated as the product $\eta \rho g Q H_E$ where the efficiency η is given the value of 0.8 throughout the chart.

Capacity of Large Francis Turbines

The size and capacity of some of the recently built Francis turbines is a source of wonder, they seem so enormous! The size and weight of the runners cause special problems getting them to the site, especially when rivers have to be crossed and the bridges are inadequate.

The largest installation in North America (circa 1998) is at La Grande on James Bay in eastern Canada where 22 units each rated at 333 MW have a total capacity of 7326 MW. A close competitor with the Three Gorges project is the Itaipu hydroelectric plant on the Paraná river (between Brazil and Paraguay), which has a capacity of 12,600 MW in full operation using 18 Francis turbines each sized at 700 MW.

The efficiency of large Francis turbines has gradually risen over the years and now is about 95%. There seems to be little prospect of much further improvement in efficiency as computable values of losses due to skin friction, tip leakage, and exit kinetic energy from the diffuser are reckoned to account for the remaining 5%. Raabe (1985) has given much attention to the statistics of the world's biggest turbines. It would appear at the present time that the largest hydroturbines in the world are the three vertical shaft Francis turbines installed at Grand Coulee III on the Columbia River, Washington, United States. Each of these leviathans has been uprated to 800 MW, with the delivery (or effective) head, $H_E = 87$ m, $N = 85.7$ rev/min, the runner having a diameter of $D = 9.26$ m and weighing 450 ton. Using this data in eqn. (9.1) it is easy to calculate that the power specific speed $\Omega_{sp} = 1.74$ rad.

9.3 THE PELTON TURBINE

This is the only hydraulic turbine of the impulse type now in common use. It is an efficient machine and it is particularly suited to high head applications. The rotor consists of a circular disc with a number of blades (usually called *buckets*) spaced around the periphery. One or more nozzles are mounted in such a way that each nozzle directs its jet along a tangent to the circle through the centres of the buckets. A “splitter” or ridge splits the oncoming jet into two equal streams so that, after flowing round the inner surface of the bucket, the two streams depart from the bucket in a direction nearly opposite to that of the incoming jet.

Figure 9.3 shows the runner of a Pelton turbine and Figure 9.4 shows a six-jet vertical axis Pelton turbine. Considering one jet impinging on a bucket, the appropriate velocity diagram is shown in Figure 9.5. The jet velocity at entry is c_1 and the blade speed is U so that the relative velocity at entry is $w_1 = c_1 - U$. At exit from the bucket one half of the jet stream flows as shown in the velocity diagram, leaving with a relative velocity w_2 and at an angle β_2 to the original direction of flow. From the velocity diagram the much smaller absolute exit velocity c_2 can be determined.

From Euler's turbine equation, eqn. (1.18c), the specific work done by the water is

$$\Delta W = U_1 c_{\theta 1} - U_2 c_{\theta 2}.$$

For the Pelton turbine, $U_1 = U_2 = U$, $c_{\theta 1} = c_1$ so we get

$$\Delta W = U[U + w_1 - (U + w_2 \cos \beta_2)] = U(w_1 - w_2 \cos \beta_2),$$

in which the value of $c_{\theta 2} < 0$, as defined in Figure 9.5, i.e., $c_{\theta 2} = U + w_2 \cos \beta_2$.

The effect of friction on the fluid flowing inside the bucket will cause the relative velocity at outlet to be less than the value at inlet. Writing $w_2 = kw_1$, where $k < 1$,

$$\Delta W = U w_1 (1 - k \cos \beta_2) = U (c_1 - U) (1 - k \cos \beta_2). \quad (9.2)$$

An efficiency η_R for the runner can be defined as the specific work done ΔW divided by the incoming kinetic energy, i.e.,

$$\eta_R = \Delta W / \left(\frac{1}{2} c_1^2 \right) = 2U(c_1 - U)(1 - k \cos \beta_2) / c_1^2. \quad (9.3)$$

**FIGURE 9.3**

Pelton Turbine Runner (Courtesy Sulzer Hydro Ltd., Zurich)

Therefore,

$$\eta_R = 2v(1 - v)(1 - k \cos \beta_2), \quad (9.4)$$

where the blade speed to jet speed ratio, $v = U/c_1$.

To find the optimum efficiency, differentiate eqn. (9.4) with respect to the blade speed ratio, i.e.,

$$\frac{d\eta_R}{dv} = 2 \frac{d}{dv} (v - v^2)(1 - k \cos \beta_2) = 2(1 - 2v)(1 - k \cos \beta_2) = 0.$$

Therefore, the maximum efficiency of the runner occurs when $v = 0.5$, i.e., $U = c_1/2$. Hence,

$$\eta_{R \max} = (1 - k \cos \beta_2). \quad (9.5)$$

**FIGURE 9.6**

Theoretical Variation of Runner Efficiency for a Pelton Wheel with a Blade Speed–Jet Speed Ratio for several Values of Friction Factor k

Figure 9.6 shows the theoretical variation of the runner efficiency with blade speed ratio for assumed values of $k = 0.8, 0.9$, and 1.0 with $\beta_2 = 165^\circ$. In practice the value of k is usually found to be between 0.8 and 0.9 .

A Simple Hydroelectric Scheme

The layout of a Pelton turbine hydroelectric scheme is shown in Figure 9.7. The water is delivered from a constant level reservoir at an elevation z_R (above sea level) and flows via a pressure tunnel to the penstock head, down the penstock to the turbine nozzles emerging onto the buckets as a high speed jet. To reduce the deleterious effects of large pressure surges, a *surge tank* is connected to the flow close to the penstock head, which acts so as to damp out transients. The elevation of the nozzles is z_N and the gross head, $H_G = z_R - z_N$.

Controlling the Speed of the Pelton Turbine

The Pelton turbine is usually directly coupled to an electrical generator that must run at synchronous speed. With large size hydroelectric schemes supplying electricity to a national grid it is essential for both the voltage and the frequency to closely match the grid values. To ensure that the turbine runs at constant speed despite any load changes that may occur, the rate of flow Q is changed. A spear (or needle) valve, Figure 9.8(a), whose position is controlled by means of a servomechanism, is moved axially within the nozzle to alter the diameter of the jet. This works well for very gradual changes in load. However, when a sudden loss in load occurs a more rapid response is needed. This is accomplished by temporarily deflecting the jet with a deflector plate so that some of the water does not reach the buckets, Figure 9.8(b). This acts to prevent over-speeding and allows time for the slower acting spear valve to move to a new position.

FIGURE 9.7

Pelton Turbine Hydroelectric Scheme

FIGURE 9.8

Methods of Regulating the Speed of a Pelton Turbine: (a) with a Spear (or Needle) Valve; (b) with a Deflector Plate

It is vital to ensure that the spear valve *does move slowly* as a sudden reduction in the rate of flow could result in serious damage to the system from pressure surges (called *water hammer*). If the spear valve did close quickly, all the kinetic energy of the water in the penstock would be absorbed by the elasticity of the supply pipeline (penstock) and the water, creating very large stresses, which would reach their greatest intensity at the turbine inlet where the pipeline is already heavily stressed. The surge chamber, shown in Figure 9.7, has the function of absorbing and dissipating some of the pressure and energy fluctuations created by too rapid a closure of the needle valve.

Sizing the Penstock

It is shown in elementary textbooks on fluid mechanics, e.g., Shames (1992) and Douglas, Gasiorek, and Swaffield (1995), that the loss in head with incompressible, steady, turbulent flow in pipes of circular cross-section is given by Darcy's equation:

$$H_f = \frac{2flV^2}{gd}, \quad (9.6)$$

where f is the friction factor, l is the length of the pipe, d is the pipe diameter, and V is the mass average velocity of the flow in the pipe. It is assumed, of course, that the pipe is running full. The value of the friction factor has been determined for various conditions of flow and pipe surface roughness and the results are usually presented in what is called a *Moody diagram*. This diagram gives values of f as a function of pipe Reynolds number for varying levels of relative roughness of the pipe wall.

The penstock (the pipeline bringing the water to the turbine) is long and of large diameter and this can add significantly to the total cost of a hydroelectric power scheme. Using Darcy's equation it is easy to calculate a suitable pipe diameter for such a scheme if the friction factor is known and an estimate can be made of the allowable head loss. Logically, this head loss would be determined on the basis of the cost of materials etc., needed for a large diameter pipe and compared with the value of the useful energy lost from having too small a pipe. A commonly used compromise for the loss in head in the supply pipes is to allow $H_f \leq 0.1 H_G$.

From eqn. (9.6), substituting for the velocity, $V = 4Q/(\pi d^2)$, we get

$$H_f = \left(\frac{32fl}{\pi^2 g} \right) \frac{Q^2}{d^5}. \quad (9.7)$$

EXAMPLE 9.1

Water is supplied to a turbine at the rate $Q = 2.272 \text{ m}^3/\text{s}$ by a single penstock 300 m long. The allowable head loss due to friction in the pipe amounts to 20 m. Determine the diameter of the pipe if the friction factor $f = 0.01$.

Solution

Rearranging eqn. (9.7)

$$d^5 = \frac{32fl}{gH_f} \left(\frac{Q}{\pi} \right)^2 = \frac{32 \times 0.01 \times 300}{9.81 \times 20} \left(\frac{2.272}{\pi} \right)^2 = 0.2559.$$

Therefore, $d = 0.7614 \text{ m}$.

Energy Losses in the Pelton Turbine

Having accounted for the energy loss due to friction in the penstock, the energy losses in the rest of the hydroelectric scheme must now be considered. The effective head, H_E (or delivered head), at entry to the turbine is the gross head minus the friction head loss, H_f , i.e.,

$$H_E = H_G - H_f = z_R - z_N - H_f$$

and the spouting (or ideal) velocity, c_o , is

$$c_o = \sqrt{2gH_E}.$$

The pipeline friction loss H_f is regarded as an external loss and is not usually included in the losses attributed to the turbine itself. The performance and efficiency of the turbine are, in effect, measured against the total head, H_E , as shown in the following.

The main energy losses of the turbine occur in

- (i) the nozzles due to fluid friction;
- (ii) converting the kinetic energy of the jet into mechanical energy of the runner;
- (iii) external effects (bearing friction and windage).

Each of these energy losses are now considered in turn.

For *item (i)* let the loss in head in the nozzles be ΔH_N . Thus, the available head is

$$H_E - \Delta H_N = c_1^2 / (2g), \quad (9.8)$$

where c_1 is the actual velocity of the jet at nozzle exit. The nozzle efficiency is defined by

$$\eta_N = \frac{\text{energy at nozzle exit}}{\text{energy at nozzle inlet}} = \frac{c_1^2}{2gH_E}. \quad (9.9a)$$

This efficiency is usually very close to 100% as the flow is accelerating through the nozzle. An often-used alternative to η_N is the nozzle velocity coefficient K_N defined by

$$K_N = \frac{\text{actual velocity at nozzle exit}}{\text{spouting velocity}} = \frac{c_1}{c_o},$$

i.e.,

$$\eta_N = K_N^2 = \frac{c_1^2}{c_o^2}. \quad (9.9b)$$

For *item (ii)* the loss in energy is already described in eqn. (9.2) and the runner efficiency η_R by eqns. (9.3) and (9.4). The turbine hydraulic efficiency η_h is defined as the specific work done by the rotor, ΔW , divided by the specific energy available at entry to the nozzle, gH_E , i.e.,

$$\eta_h = \frac{\Delta W}{gH_E} = \left(\frac{\Delta W}{\frac{1}{2}c_1^2} \right) \left(\frac{\frac{1}{2}c_1^2}{gH_E} \right) = \eta_R \eta_N, \quad (9.10)$$

after using eqn. (9.9a).

For item (iii) the external losses are responsible for the energy deficit between the runner and the shaft. A good estimate of these losses can be made using the following simple flow model where the specific energy loss is assumed to be proportional to the square of the blade speed, i.e.,

$$\text{external loss/unit mass flow} = KU^2,$$

where K is a dimensionless constant of proportionality. Thus, the shaft work done/unit mass flow is

$$\Delta W - KU^2.$$

Therefore, the overall efficiency of the turbine, η_o , including these external losses is

$$\eta_o = (\Delta W - KU^2)/(gH_e),$$

i.e., the shaft work delivered by the turbine/specific energy available at nozzle entry, which

$$= \eta_R \eta_N - 2K \left(\frac{U}{c_1} \right)^2 \left(\frac{c_1^2}{2gH_E} \right).$$

Using the definitions of the blade speed–jet speed ratio, $v = U/c_1$, and the nozzle efficiency, $\eta_N = c_1^2/c_2^2$,

$$\eta_0 = \eta_N(\eta_R - 2Kv^2) = \eta_m \eta_R \eta_N, \quad (9.11)$$

where the mechanical efficiency, $\eta_m = 1 - \text{external losses}/gH_E$, i.e.,

$$\eta_m = 1 - 2Kv^2/\eta_R. \quad (9.12)$$

The variation of the overall efficiency as given by eqn. (9.11) is shown in Figure 9.9 as a function of v for several values of the windage coefficient K . It will be noticed that peak efficiency reduces as the value of K is increased and that it occurs at lower values of v than the optimum for the runner. This evaluation of the theoretical performance of a Pelton turbine gives a possible reason for the often puzzling result given when experiments are evaluated and that always yield a peak efficiency for values of $v < 0.5$.

FIGURE 9.9

Variation of Overall Efficiency of a Pelton Turbine with Speed Ratio for Several Values of Windage Coefficient, K

By differentiating eqn. (9.11) it can be shown that the optimum value of v occurs when

$$v_{\text{opt}} = \frac{A}{2(A + K)}.$$

where $A = 1 - k \cos \beta_2$.

Exercise

Let $k = 0.9$, $\beta_2 = 165^\circ$, and $K = 0.1$. Hence, $A = 1.869$ and $v = 0.475$.

Typical performance of a Pelton turbine *under conditions of constant head and speed* is shown in Figure 9.10 in the form of the variation of overall efficiency against load ratio. As a result of a change in the load the output of the turbine must then be regulated by a change in the setting of the needle valve to keep the turbine speed constant. The observed almost constant value of the efficiency over most of the load range is the result of the *hydraulic losses* reducing in proportion to the power output. However, as the load ratio is reduced to even lower values, the windage and bearing friction losses, which have not diminished, assume a relatively greater importance and the overall efficiency rapidly diminishes towards zero.

EXAMPLE 9.2

A Pelton turbine is driven by two jets, generating 4.0 MW at 375 rev/min. The effective head at the nozzles is 200 m of water and the nozzle velocity coefficient, $K_N = 0.98$. The axes of the jets are tangent to a circle 1.5 m in diameter. The relative velocity of the flow across the buckets is decreased by 15% and the water is deflected through an angle of 165° .

Neglecting bearing and windage losses, determine

- (i) the runner efficiency;
- (ii) the diameter of each jet;
- (iii) the power specific speed.

FIGURE 9.10

Pelton Turbine Overall Efficiency Variation with Load Under Constant Head and Constant Speed Conditions

Solution

- (i) The blade speed is

$$U = \Omega r = (375 \times \pi / 30) \times 1.5 / 2 = 39.27 \times 1.5 / 2 = 29.45 \text{ m/s.}$$

The jet speed is

$$c_1 = K_N \sqrt{2gH_E} = 0.98 \times \sqrt{2 \times 9.81 \times 200} = 61.39 \text{ m/s.}$$

Therefore, $v = U/c_1 = 0.4798$.

The efficiency of the runner is obtained from eqn. (9.4):

$$\eta_R = 2 \times 0.4798 \times (1 - 0.4798)(1 - 0.85 \times \cos 165^\circ) = 0.9090.$$

- (ii) The “theoretical” power is
- $P_{th} = P/\eta_R = 4.0/0.909 = 4.40 \text{ MW}$
- , where
- $P_{th} = \rho g Q H_E$
- . Therefore,

$$Q = P_{th}/(\rho g H_E) = 4.4 \times 10^6 / (9810 \times 200) = 2.243 \text{ m}^3/\text{s.}$$

Each jet must have a flow area of

$$A_j = \frac{Q}{2c_1} = 2.243 / (2 \times 61.39) = 0.01827 \text{ m}^2.$$

Therefore, $d_j = 0.5125 \text{ m}$.

- (iii) Substituting into eqn. (9.1), the power specific speed is

$$\Omega_{sp} = 39.27 \times \left(\frac{4.0 \times 10^6}{10^3} \right)^{\frac{1}{2}} / (9.81 \times 200)^{\frac{5}{4}} = 0.190 \text{ rad.}$$

9.4 REACTION TURBINES

The primary features of the reaction turbine are

- (i) only part of the overall pressure drop has occurred up to turbine entry, the remaining pressure drop takes place in the turbine itself;
- (ii) the flow completely fills all of the passages in the runner, unlike the Pelton turbine where, for each jet, only one or two of the buckets at a time are in contact with the water;
- (iii) pivotable guide vanes are used to control and direct the flow;
- (iv) a draft tube is normally added on to the turbine exit; this is considered as an integral part of the turbine.

The pressure of the water gradually decreases as it flows through the runner and the reaction from this pressure change earns this type of turbine its appellation.

9.5 THE FRANCIS TURBINE

The majority of Francis turbines are arranged so that the axis is vertical (some smaller machines can have horizontal axes). Figure 9.11 illustrates a section through a vertical shaft Francis turbine with a runner diameter of 5 m, a head of 110 m, and a power rating of nearly 200 MW. Water enters via a

**FIGURE 9.11**

Vertical Shaft Francis Turbine: Runner Diameter 5 m, Head 110 m, Power 200 MW (Courtesy Sulzer Hydro Ltd., Zurich)

spiral casing called a *volute* or *scroll* that surrounds the runner. The area of cross-section of the volute decreases along the flow path in such a way that the flow velocity remains constant. From the volute the flow enters a ring of stationary guide vanes, which direct it onto the runner at the most appropriate angle.

In flowing through the runner the angular momentum of the water is reduced and work is supplied to the turbine shaft. At the design condition the absolute flow leaves the runner axially (although a small amount of swirl may be countenanced) into the *draft tube* and, finally, the flow enters the *tail-race*. It is essential that the exit of the draft tube is submerged below the level of the water in the tail-race in order that the turbine remains full of water. The draft tube also acts as a diffuser; by careful design it can ensure maximum recovery of energy through the turbine by significantly reducing the exit kinetic energy.

Figure 9.12 shows the runner of a small Francis turbine and Figure 9.13 is a sectional view of the turbine together with the velocity triangles at inlet to and exit from the runner at mid-blade height. At inlet to the guide vanes the flow is in the radial/tangential plane, the absolute velocity is c_1 and the absolute flow angle is α_1 . Thus,

$$\alpha_1 = \tan^{-1}(c_{\theta 1}/c_{r1}). \quad (9.13)$$

**FIGURE 9.12**

Runner of a Small Francis Turbine (Permission Granted to Copy Under the Terms of the GNU Free Documentation License)

The flow is turned to angle α_2 and velocity c_2 , the absolute condition of the flow at entry to the runner. By vector subtraction the relative velocity at entry to the runner is found, i.e., $w_2 = c_2 - U_2$. The relative flow angle β_2 at inlet to the runner is defined as

$$\beta_2 = \tan^{-1}[(c_{\theta 2} - U_2)/c_{r2}]. \quad (9.14)$$

Further inspection of the velocity diagrams in Figure 9.13 reveals that the direction of the velocity vectors approaching both guide vanes and runner blades are tangential to the camber lines at the leading edge of each row. This is the ideal flow condition for “shockless” low loss entry, although an incidence of a few degrees may be beneficial to output without a significant extra loss penalty. At vane outlet some deviation from the blade outlet angle is to be expected (see Chapter 3). For these reasons, in all problems concerning the direction of flow, it is clear that the angle of the fluid flow is important and not the vane angle as is often quoted in other texts.

At outlet from the runner the flow plane is simplified as though it were actually in the radial/tangential plane. This simplification will not affect the subsequent analysis of the flow but it must be conceded that some component of velocity in the axial direction does exist at runner outlet.

The water leaves the runner with a relative flow angle β_3 and a relative flow velocity w_3 . The absolute velocity at runner exit is found by vector addition, i.e., $c_3 = w_3 + U_3$. The relative flow angle, β_3 , at runner exit is given by

$$\beta_3 = \tan^{-1}[(c_{\theta 3} + U_3)/c_{r3}]. \quad (9.15)$$

**FIGURE 9.13**

Sectional Sketch of Blading for a Francis Turbine Showing Velocity Diagrams at Runner Inlet and Exit

In this equation it is assumed that some residual swirl velocity $c_{\theta 3}$ is present (c_{r3} is the radial velocity at exit from the runner). In most simple analyses of the Francis turbine it is assumed that there is no exit swirl. Detailed investigations have shown that some extra *counter-swirl* (i.e., acting so as to increase Δc_θ) at the runner exit does increase the amount of work done by the fluid without a significant reduction in turbine efficiency.

When a Francis turbine is required to operate at part load, the power output is reduced by swivelling the guide vanes to restrict the flow, i.e., Q is reduced, while the blade speed is maintained constant. Figure 9.14 compares the velocity triangles at full load and at part load from which it will be seen that the relative flow at runner entry is at a high incidence and at runner exit the absolute flow has a large component of swirl. Both of these flow conditions give rise to high head losses. Figure 9.15 shows the variation of hydraulic efficiency for several types of turbine, including the Francis turbine, over the full load range at constant speed and constant head.

It is of interest to note the effect that swirling flow has on the performance of the following diffuser. The results of an extensive experimental investigation made by McDonald, Fox, and van Dwoestine (1971) showed that swirling inlet flow *does not* affect the performance of conical diffusers, which are well designed and give unseparated or only slightly separated flow when the flow through them is entirely axial. Accordingly, part load operation of the turbine is unlikely to give adverse diffuser performance.

FIGURE 9.14

Comparison of Velocity Triangles for a Francis Turbine at Full Load and at Part Load Operation

FIGURE 9.15

Variation of Hydraulic Efficiency for Various Types of Turbine over a Range of Loading, at Constant Speed and Constant Head

Basic Equations

Euler's turbine equation, eqn. (1.18c), in the present notation, is written as

$$\Delta W = U_2 c_{\theta 2} - U_3 c_{\theta 3}. \quad (9.16a)$$

FIGURE 9.16

Location of Draft Tube in Relation to Vertical Shaft Francis Turbine

If the flow at runner exit is without swirl then the equation reduces to

$$\Delta W = U_2 c_{\theta 2}. \quad (9.16b)$$

The effective head for all reaction turbines, H_E , is the total head available at the turbine inlet *relative to the surface of the tailrace*. At entry to the runner the energy available is equal to the sum of the kinetic, potential and pressure energies:

$$g(H_E - \Delta H_N) = \frac{p_2 - p_a}{\rho} + \frac{1}{2} c_2^2 + g z_2, \quad (9.17)$$

where ΔH_N is the loss of head due to friction in the volute and guide vanes and p_2 is the *absolute* static pressure at inlet to the runner.

At runner outlet the energy in the water is further reduced by the amount of specific work ΔW and by friction work in the runner, $g\Delta H_R$ and this remaining energy equals the sum of the pressure potential and kinetic energies:

$$g(H_E - \Delta H_N - \Delta H_R) - \Delta W = \frac{1}{2} c_3^2 + p_3/\rho - p_a/\rho + g z_3, \quad (9.18)$$

where p_3 is the *absolute* static pressure at runner exit.

By differencing eqns. (9.17) and (9.18), the specific work is obtained:

$$\Delta W = (p_{02} - p_{03})/\rho - g\Delta H_R + g(z_2 - z_3), \quad (9.19)$$

where p_{02} and p_{03} are the absolute total pressures at runner inlet and exit.

Figure 9.16 shows the draft tube in relation to a vertical-shaft Francis turbine. The most important dimension in this diagram is the vertical distance ($z = z_3$) between the exit plane of the runner and the

free surface of the tailrace. The energy equation between the exit of the runner and the tailrace can now be written as

$$p_3/\rho + \frac{1}{2}c_3^2 + gz_3 - g\Delta H_{DT} = \frac{1}{2}c_4^2 + p_a/\rho, \quad (9.20)$$

where ΔH_{DT} is the loss in head in the draft tube and c_4 is the flow exit velocity.

The hydraulic efficiency is defined by

$$\eta_h = \frac{\Delta W}{gH_E} = \frac{U_2 c_{\theta 2} - U_3 c_{\theta 3}}{gH_E} \quad (9.21a)$$

and, whenever $c_{\theta 3} = 0$,

$$\eta_H = \frac{U_2 c_{\theta 2}}{gH_E}. \quad (9.21b)$$

The overall efficiency is given by $\eta_o = \eta_m \eta_H$. For very large turbines (e.g., 500–1000 MW) the mechanical losses are then relatively small, $\eta \rightarrow 100\%$ and effectively $\eta_o \approx \eta_H$.

For the Francis turbine the ratio of the runner tip speed to the jet velocity, $v = U_2/c_1$, is not as critical for high efficiency operation as it is for the Pelton turbine and can lie in a fairly wide range, e.g., $0.6 \leq v \leq 0.95$. In most applications the Francis turbine is used to drive a synchronous generator and the rotational speeds chosen are those appropriate to either 50 or 60 cycles per second. The speed must then be maintained constant.

It is possible to obtain part load operation of the turbine by varying the angle of the guide vanes. The guide vanes are pivoted and set to an optimum angle via a gearing mechanism. However, part load operation normally causes a whirl velocity to be set up in the flow downstream of the runner causing a reduction in efficiency. The strength of the vortex may be enough to cause a cavitation bubble to form along the axis of the draft tube. (See Section 9.8, Cavitation.)

EXAMPLE 9.3

In a vertical-shaft Francis turbine the available head at the inlet flange is 150 m of water and the vertical distance between the runner and the tailrace is 2.0 m. The runner tip speed is 35 m/s, the meridional velocity of the water through the runner is constant at 10.5 m/s, the flow leaves the runner without whirl and the velocity at exit from the draft tube is 3.5 m/s.

The hydraulic losses for the turbine are as follows:

$$\Delta H_N = 6.0 \text{ m}, \quad \Delta H_R = 10 \text{ m}, \quad \Delta H_{DT} = 1.0 \text{ m}.$$

Determine

- (i) the specific work, ΔW , and the hydraulic efficiency, η_h , of the turbine;
- (ii) the absolute velocity, c_2 , at runner entry;
- (iii) the pressure head (relative to the tailrace) at inlet to and exit from the runner;
- (iv) the absolute and relative flow angles at runner inlet;
- (v) if the flow discharged by the turbine is $20 \text{ m}^3/\text{s}$ and the power specific speed is 0.8 (rad), the speed of rotation and diameter of the runner.

Solution

From eqns. (9.18) and (9.20), we can find the specific work,

$$\begin{aligned}\Delta W &= g(H_E - \Delta H_N - \Delta H_R - \Delta H_{DT}) - \frac{1}{2}c_4^2 \\ &= 9.81 \times (150 - 6 - 10 - 1) - 3.5^2/2 = 1298.6 \text{ m}^2/\text{s}^2.\end{aligned}$$

The hydraulic efficiency, $\eta_h = \Delta W/(gH_E) = 0.8825$.

As $c_{\theta 3} = 0$, then $\Delta W = U_2 c_{\theta 2}$ and $c_{\theta 2} = \Delta W/U_2 = 1298.6/35 = 37.1 \text{ m/s}$, thus,

$$c_2 = \sqrt{c_{\theta 2}^2 + c_m^2} = \sqrt{37.1^2 + 10.5^2} = 38.56 \text{ m/s}.$$

From eqn. (9.17) the pressure head at inlet to the runner is

$$H_2 = H_E - \Delta H_N - c_2^2/(2g) = 150 - 6 - 38.56^2/(2 \times 9.81) = 68.22 \text{ m}.$$

Again, using eqn. (9.20), the pressure head (relative to the tailrace) at runner exit is

$$H_3 = (p_3 - p_a)/(\rho g) = (c_4^2 - c_3^2)/(2g) + \Delta H_{DT} - z_3 = (3.5^2 - 10.5^2)/(2 \times 9.81) + 1 - 2 = -6.0 \text{ m}.$$

Note: The minus sign for H_3 indicates that the pressure is below the atmospheric level. This is a matter of considerable importance in the design and operation of hydraulic turbomachinery and is considered in further detail under the heading Cavitation later in this chapter.

The flow angles at runner inlet are now obtained as follows:

$$\alpha_2 = \tan^{-1}(c_{\theta 2}/c_{r2}) = \tan^{-1}(37.1/10.5) = 74.2^\circ$$

$$\beta_2 = \tan^{-1}[(c_{\theta 2} - U_2)/c_{r2}] = \tan^{-1}[(37.1 - 35)/10.5] = 11.31^\circ.$$

From the definition of power specific speed, eqn. (9.1), and using $P/\rho = Q\Delta W$,

$$\Omega = \frac{\Omega_{SP}(gH_E)^{\frac{5}{4}}}{\sqrt{Q\Delta W}} = \frac{0.8 \times 9114}{\sqrt{20 \times 1298.7}} = 45.24 \text{ rad/s}.$$

Thus, the rotational speed $N = 432 \text{ rev/min}$ and the runner diameter is

$$D_2 = 2U_2/\Omega = 70/45.24 = 1.547 \text{ m}.$$

9.6 THE KAPLAN TURBINE

This type of turbine evolved from the need to generate power from much lower pressure heads than are normally employed with the Francis turbine. To satisfy large power demands very large volume flow rates need to be accommodated in the Kaplan turbine, i.e., the product QH_E is large. The overall flow configuration is from radial to axial. Figure 9.17(a) is a part sectional view of a Kaplan turbine in which the flow enters from a volute into the inlet guide vanes, which impart a degree of swirl to

**FIGURE 9.17**

(a) Part Section of a Kaplan Turbine in Situ; (b) Kaplan Turbine Runner (Courtesy Sulzer Hydro Ltd., Zurich)

the flow determined by the needs of the runner. The flow leaving the guide vanes is forced by the shape of the passage into an axial direction and the swirl becomes essentially a free vortex, i.e.,

$$rc_{\theta} = \text{a constant.}$$

The vanes of the runner are similar to those of an axial-flow turbine rotor but designed with a twist suitable for the free-vortex flow at entry and an axial flow at outlet. A picture of a Kaplan (or propeller) turbine runner is shown in Figure 9.17(b). Because of the very high torque that must be transmitted and the large length of the blades, strength considerations impose the need for large blade chords. As a result, pitch–chord ratios of 1.0 to 1.5 are commonly used by manufacturers and, consequently, the number of blades is small, usually four, five, or six. The Kaplan turbine incorporates one essential feature not found in other turbine rotors and that is the setting of the stagger angle can be controlled. At part load operation the setting angle of the runner vanes is adjusted automatically by a servomechanism to maintain optimum efficiency conditions. This adjustment requires a complementary adjustment of the inlet guide vane stagger angle to maintain an absolute axial flow at exit from the runner.

Basic Equations

Most of the equations presented for the Francis turbine also apply to the Kaplan (or propeller) turbine, apart from the treatment of the runner. Figure 9.18 shows the velocity triangles and part section of a Kaplan turbine drawn for the mid-blade height. At exit from the runner the flow is shown leaving the runner without a whirl velocity, i.e., $c_{\theta 3} = 0$ and constant axial velocity. The theory of free-vortex flows was expounded in Chapter 6 and the main results as they apply to an incompressible fluid are given here. The runner blades will have a fairly high degree of twist, the amount depending upon the

**FIGURE 9.18**

Section of a Kaplan Turbine and Velocity Diagrams at Inlet to and Exit from the Runner

strength of the circulation function K and the magnitude of the axial velocity. Just upstream of the runner the flow is assumed to be a free-vortex and the velocity components are accordingly

$$c_{\theta 2} = K/r, \quad c_x = \text{a constant.}$$

The relations for the flow angles are

$$\tan \beta_2 = U/c_x - \tan \alpha_2 = \Omega r/c_x - K/(rc_x), \quad (9.22a)$$

$$\tan \beta_3 = U/c_x = \Omega r/c_x. \quad (9.22b)$$

EXAMPLE 9.4

A small-scale Kaplan turbine has a power output of 8 MW, an available head at turbine entry of 13.4 m, and a rotational speed of 200 rev/min. The inlet guide vanes have a length of 1.6 m and the diameter at the trailing edge surface is 3.1 m. The runner diameter is 2.9 m and the hub–tip ratio is 0.4.

Assuming the hydraulic efficiency is 92% and the runner design is “free-vortex,” determine

- (i) the radial and tangential components of velocity at exit from the guide vanes;
- (ii) the component of axial velocity at the runner;
- (iii) the absolute and relative flow angles upstream and downstream of the runner at the hub, mid-radius, and tip.

Solution

As $P = \eta_H \rho g Q H_E$, then the volume flow rate is

$$Q = P/(\eta_H \rho g H_E) = 8 \times 10^6 / (0.92 \times 9810 \times 13.4) = 66.15 \text{ m}^3/\text{s}^2$$

Therefore,

$$c_{r1} = Q/(2\pi r_1 L) = 66.15/(2\pi \times 1.55 \times 1.6) = 4.245 \text{ m/s},$$

$$c_{x2} = \frac{4Q}{\pi D_{2t}^2 (1 - v^2)} = 4 \times 66.15/(\pi \times 2.9^2 \times 0.84) = 11.922 \text{ m/s}.$$

As the specific work done is $\Delta W = U_2 c_{\theta 2}$ and $\eta_H = \Delta W/(gH_E)$, then at the tip

$$c_{\theta 2} = \frac{\eta_H g H_E}{U_2} = \frac{0.92 \times 9.81 \times 13.4}{30.37} = 3.892 \text{ m/s},$$

where the blade tip speed is $U_2 = \Omega D_2/2 = (200 \times \pi/30) \times 2.9/2 = 30.37 \text{ m/s}$,

$$c_{\theta 1} = c_{\theta 2} r_2/r_1 = 3.892 \times 1.45/1.55 = 3.725 \text{ m/s}^2,$$

$$\alpha_1 = \tan^{-1}\left(\frac{c_{\theta 1}}{c_{r1}}\right) = \tan^{-1}\left(\frac{3.725}{4.245}\right) = 41.26^\circ.$$

Values α_2 , β_2 and β_3 shown in Table 9.4 have been derived from the following relations:

$$\alpha_2 = \tan^{-1}\left(\frac{c_{\theta 2}}{c_{x2}}\right) = \tan^{-1}\left(\frac{c_{\theta 2t} r_t}{c_{x2} r}\right),$$

$$\beta_2 = \tan^{-1}\left(\frac{\Omega r}{c_{x2}} - \tan \alpha_2\right) = \tan^{-1}\left(\frac{U_{2t} r}{c_{x2} r_t} - \tan \alpha_2\right),$$

$$\beta_3 = \tan^{-1}\left(\frac{U}{c_{x2}}\right) = \tan^{-1}\left(\frac{U_{2t} r}{c_{x2} r_t}\right).$$

Finally, Figure 9.19 illustrates the variation of the flow angles, from which the large amount of blade twist mentioned earlier can be inferred.

Table 9.4 Calculated Values of Flow Angles for Example 9.4

Parameter	Ratio r/r_t		
	0.4	0.7	1.0
$c_{\theta 2}$ (m/s)	9.955	5.687	3.982
$\tan \alpha_2$	0.835	0.4772	0.334
α_2 (deg)	39.86	25.51	18.47
U/c_{x2}	1.019	1.7832	2.547

β_3 (deg)	45.54	60.72	68.57

**FIGURE 9.19**

Calculated Variation of Flow Angles for Kaplan Turbine of Example 9.4

9.7 EFFECT OF SIZE ON TURBOMACHINE EFFICIENCY

Despite careful attention to detail at the design stage and during manufacture it is a fact that small turbomachines always have lower efficiencies than larger geometrically similar machines. The primary reason for this is that it is not possible to establish perfect dynamical similarity between turbomachines of different size. To obtain this condition, each of the dimensionless terms in eqns. (2.2) would need to be the same for all sizes of a machine.

To illustrate this consider a family of turbomachines where the loading term, $\psi = gH/N^2D^2$, is the same and the Reynolds number, $Re = ND^2/\nu$, is the same for every size of machine, then

$$\psi Re^2 = \frac{gH}{N^2D^2} \times \frac{N^2D^4}{\nu^2} = \frac{gHD^2}{\nu^2}$$

must be the same for the whole family. Thus, for a given fluid (ν is a constant), a reduction in size D must be followed by an increase in the head H . A turbine model of one eighth the size of a prototype would need to be tested with a head 64 times that required by the prototype! Fortunately, the effect on the model efficiency caused by changing the Reynolds number is not large. In practice, models are normally tested at conveniently low heads and an empirical correction is applied to the efficiency.

With model testing other factors affect the results. Exact geometric similarity cannot be achieved for the following reasons:

- (i) the blades in the model will probably be thicker than in the prototype;
- (ii) the relative surface roughness for the model blades will be greater;
- (iii) leakage losses around the blade tips of the model will be relatively greater as a result of increased relative tip clearances.

Various simple corrections have been devised (see Addison, 1964) to allow for the effects of size (or scale) on the efficiency. One of the simplest and best known is that due to Moody and Zowski (1969),

also reported by Addison (1964) and Massey (1979), which as applied to the efficiency of reaction turbines is

$$\frac{1 - \eta_p}{1 - \eta_m} = \left(\frac{D_m}{D_p} \right)^n, \quad (9.23)$$

where the subscripts p and m refer to prototype and model, and the index n is in the range 0.2 to 0.25. From comparison of field tests of large units with model tests, Moody and Zowski concluded that the best value for n was approximately 0.2 rather than 0.25 and for general application this is the value used. However, Addison (1964) reported tests done on a full-scale Francis turbine and a model made to a scale of 1 to 4.54 that gave measured values of the maximum efficiencies of 0.85 and 0.90 for the model and full-scale turbines, respectively, which agreed very well with the ratio computed with $n = 0.25$ in the Moody formula!

EXAMPLE 9.5

A model of a Francis turbine is built to a scale of one fifth of full size and when tested it developed a power output of 3 kW under a head of 1.8 m of water, at a rotational speed of 360 rev/min and a flow rate of 0.215 m³/s. Estimate the speed, flow rate, and power of the full-scale turbine when working under dynamically similar conditions with a head of 60 m of water.

By making a suitable correction for scale effects, determine the efficiency and the power of the full-size turbine. Use Moody's formula and assume $n = 0.25$.

Solution

From the group $\psi = gH/(ND)^2$ we get

$$N_p = N_m(D_m/D_p)(H_p/H_m)^{0.5} = (360/5)(60/1.8)^{0.5} = 415.7 \text{ rev/min.}$$

From the group $\phi = Q/(ND^3)$ we get

$$Q_p = Q_m(N_p/N_m)(D_p/D_m)^3 = 0.215 \times (415.7/360) \times 5^3 = 31.03 \text{ m}^3/\text{s.}$$

Lastly, from the group $\hat{P} = P/(\rho N^3 D^5)$ we get

$$P_p = P_m(N_p/N_m)^3(D_p/D_m)^5 = 3 \times (415.7)^3 \times 5^5 = 14,430 \text{ kW} = 14.43 \text{ MW.}$$

This result has still to be corrected to allow for scale effects. First we must calculate the efficiency of the model turbine. The efficiency is found from

$$\eta_m = P/(\rho Q g H) = 3 \times 10^3 / (10^3 \times 0.215 \times 9.81 \times 1.8) = 0.79.$$

Using Moody's formula the efficiency of the prototype is determined:

$$(1 - \eta_p) = (1 - \eta_m) \times 0.2^{0.25} = 0.21 \times 0.6687,$$

hence,

$$\eta_p = 0.8596.$$

The corresponding power is found by an adjustment of the original power obtained under dynamically similar conditions, i.e.,

$$\text{corrected } P_p = 14.43 \times 0.8596/0.79 = 15.7 \text{ MW.}$$

9.8 CAVITATION

A description of the phenomenon of cavitation with regard to pumps was given in Chapter 7. In hydraulic turbines, where reliability, long life, and efficiency are all very important, the effects of cavitation must be considered. Two types of cavitation may be in evidence:

- (i) on the suction surfaces of the runner blades at outlet that can cause severe blade erosion;
- (ii) a twisting “rope type” cavity that appears in the draft tube at off-design operating conditions.

Cavitation in hydraulic turbines can occur on the suction surfaces of the runner blades where the dynamic action of the blades acting on the fluid creates low pressure zones in a region where the static pressure is already low. Hydraulic turbines are designed to run for many years with very little maintenance. However, if cavitation does occur then pitting of the surfaces, fatigue cracking, and partial collapse of the blades will reduce performance. Figure 9.20 shows extensive damage due to cavitation of a Francis runner.

Cavitation will commence when the local static pressure is less than the vapour pressure of the water, i.e., where the head is low, the velocity is high and the elevation, z , of the turbine is set too high above the tailrace. For a turbine with a horizontal shaft the lowest pressure will be located in the upper part of the runner, which could be of major significance in large machines. Fortunately, the runners of

FIGURE 9.20

Cavitation Damage to the Blades of a Francis Turbine (Permission Granted to Copy Under the Terms of the GNU Free Documentation License)

large machines are, in general, made so that their shafts are orientated vertically, lessening the problem of cavitation occurrence.

The cavitation performance of hydraulic turbines can be correlated with the Thoma coefficient, σ , defined as

$$\sigma = \frac{H_S}{H_E} = \frac{(p_a - p_v)/(\rho g) - z}{H_E}, \quad (9.24)$$

where H_S is the net positive suction head (NPSH), the amount of head needed to avoid cavitation, the difference in elevation, z , is defined in Figure 9.16 and p_v is the vapour pressure of the water. The Thoma coefficient was, strictly, originally defined in connection with cavitation in turbines and its use in pumps is not appropriate (see Yedidiah, 1981). It is to be shown that σ represents the fraction of the available head H_E , which is unavailable for the production of work. A large value of σ means that a smaller part of the available head can be utilised. In a pump, incidentally, there is no direct connection between the developed head and its suction capabilities, provided that cavitation does not occur, which is why the use of the Thoma coefficient is not appropriate for pumps.

From the energy equation, eqn. (9.20), this can be rewritten as

$$\frac{p_a - p_3}{\rho g} - z = \frac{1}{2g}(c_3^2 - c_4^2) - \Delta H_{DT}, \quad (9.25)$$

so that when $p_3 = p_v$, then H_S is equal to the right-hand side of eqn. (9.24).

Figure 9.21 shows a widely used correlation of the Thoma coefficient plotted against specific speed for Francis and Kaplan turbines, approximately defining the boundary between no cavitation and severe cavitation. In fact, there exists a wide range of critical values of σ for each value of specific speed and type of turbine due to the individual cavitation characteristics of the various runner designs. The curves drawn are meant to assist preliminary selection procedures. An alternative method for avoiding cavitation is to perform tests on a model of a particular turbine in which the value of p_3 is reduced until cavitation occurs or a marked decrease in efficiency becomes apparent. This performance reduction would correspond to the production of large-scale cavitation bubbles. The pressure at which cavitation erosion occurs will actually be at some higher value than that at which the performance reduction starts.

For the centre-line cavitation that appears downstream of the runner at off-design operating conditions, oscillations of the cavity can cause severe vibration of the draft tube. Young (1989) reported some results of a “corkscrew” cavity rotating at 4 Hz. Air injected into the flow both stabilizes the flow and cushions the vibration.

EXAMPLE 9.6

Using the data in Example 9.3 and given that the atmospheric pressure is 1.013 bar and the water is at 25°C, determine the NPSH for the turbine. Hence, using Thoma’s coefficient and the data shown in Figure 9.19, determine whether cavitation is likely to occur. Verify the result using the result given in eqn. (2.23b).

Solution

From tables of fluid properties, e.g., Rogers and Mayhew (1995), or using the data of Figure 9.22, the vapour pressure for water corresponding to a temperature of 25°C is 0.03166 bar. From the definition of NPSH, eqn. (9.24), we obtain

FIGURE 9.21

Variation of Critical Cavitation Coefficient with Non-Dimensional Specific Speed for Francis and Kaplan Turbines (Adapted from Moody and Zowski, 1969)

$$H_s = \frac{P_a - P_v}{\rho g} - z = (1.013 - 0.03166) \times 10^5 / (9810) - 2 = 8.003 \text{ m.}$$

Thus, Thoma's coefficient is, $\sigma = H_s / H_E = 8.003 / 150 = 0.05336$.

At the value of $\Omega_{sp} = 0.8$ given as data, the value of the critical Thoma coefficient σ_c corresponding to this is 0.09 from Figure 9.21. From the fact that $\sigma < \sigma_c$, then the turbine *will* cavitate.

From the definition of the suction specific speed,

$$\Omega_{ss} = \frac{\Omega Q^{1/2}}{(gH_s)^{3/4}} = \frac{44.9 \times 20^{1/2}}{(9.81 \times 8.003)^{3/4}} = 200.8 / 26.375 = 7.613.$$

**FIGURE 9.22**

Vapour Pressure of Water as Head (m) versus Temperature

According to eqn. (2.23b), when Ω_{SS} exceeds 4.0 (rad) cavitation can occur, giving further confirmation of the above conclusion.

Connection Between Thoma's Coefficient, Suction Specific Speed and Specific Speed

The definitions of suction specific speed and specific speed are

$$\Omega_{SS} = \frac{\Omega Q^{1/2}}{(gH_S)^{3/4}} \text{ and } \Omega_S = \frac{\Omega Q^{1/2}}{(gH_E)^{3/4}}.$$

Combining these expressions and using eqn. (9.24), we get

$$\frac{\Omega_S}{\Omega_{SS}} = \left(\frac{gH_S}{gH_E} \right)^{3/4} = \sigma^{3/4};$$

therefore,

$$\sigma = \left(\frac{\Omega_S}{\Omega_{SS}} \right)^{4/3}. \quad (9.26)$$

Exercise

Verify the value of Thoma's coefficient in the earlier example using the values of power specific speed, efficiency, and suction specific speed given or derived.

We use as data $\Omega_{SS} = 7.613$, $\Omega_{SP} = 0.8$, and $\eta_H = 0.896$ so that, from eqn. (2.16),

$$\Omega_S = \Omega_{SP} / \sqrt{\eta_H} = 0.8 / \sqrt{0.896} = 0.8452;$$

therefore,

$$\sigma = (0.8452/7.613)^{4/3} = 0.05336.$$

Avoiding Cavitation

By rearranging eqn. (9.24) and putting $\sigma = \sigma_c$, a critical value of z can be derived on the boundary curve between cavitation and no cavitation. Thus,

$$z = z_c = \frac{p_a - p_v}{\rho g} - \sigma_c H_E = (101.3 - 3.17)/9.81 - 0.09 \times 150 = -3.5 \text{ m}.$$

This means that the turbine would need to be submerged to a depth of 3.5 m or more below the surface of the tailwater and, for a Francis turbine, would lead to problems with regard to construction and maintenance. Equation (9.24) shows that the greater the available head H_E at which a turbine operates, the lower it must be located relative to the surface of the tailrace.

9.9 APPLICATION OF CFD TO THE DESIGN OF HYDRAULIC TURBINES

With such a long history, the design of hydraulic turbines still depends very much on the experience gained from earlier designs. According to Drtina and Sallaberger (1999), the use of computational fluid dynamics for predicting the flow in these machines has brought further substantial improvements in their hydraulic design, and resulted in a more complete understanding of the flow processes and their influence on turbine performance. Details of flow separation, loss sources, and loss distributions in components both at design and off-design as well as detecting low pressure levels associated with the risk of cavitation are now amenable to analysis with the aid of CFD.

Drtina and Sallaberger presented two examples where the application of CFD resulted in a better understanding of complex flow phenomena. Generally, this better knowledge of the flow has resulted either in design improvements to existing components or to the replacement of components by a completely new design.

9.10 THE WELLS TURBINE

Introduction

Numerous methods for extracting energy from the motion of sea-waves have been proposed and investigated since the late 1970s. The problem is in finding an efficient and economical means of converting an oscillating flow of energy into a unidirectional rotary motion for driving electrical generators. A novel solution of this problem is the Wells turbine (Wells, 1976), a version of the axial-flow turbine. For countries surrounded by the sea, such as the British Isles and Japan to mention just two, or with extensive shorelines like the United States, wave energy conversion is an attractive proposition. Energy conversion systems based on the *oscillating water column* and the Wells turbine have been installed at several locations (Islay in Scotland and at Trivandrum in India). Figure 9.23 shows the arrangement of a turbine and generator together with the oscillating column of seawater. The cross-sectional area of the

**FIGURE 9.23**

Arrangement of Wells Turbine and Oscillating Water Column (Adapted from Raghunathan et al., 1995)

plenum chamber is made very large compared to the flow area of the turbine so that a substantial air velocity through the turbine is attained.

One version of the Wells turbine consists of a rotor with eight *uncambered* aerofoil section blades set at a stagger angle of 90° (i.e., with their chord lines lying in the plane of rotation). A schematic diagram of such a Wells turbine is shown in Figure 9.24. At first sight the arrangement might seem to be a highly improbable means of energy conversion. However, once the blades have attained design speed the turbine is capable of producing a time-averaged positive power output from the *cyclically reversing airflow* with a fairly high efficiency. According to Raghunathan, Curran, and Whittaker (1995) *peak* efficiencies of 65% have been measured at the experimental wave power station on Islay. The results obtained from a theoretical analysis by Gato and Falcão (1984) showed that fairly high values of the mean efficiency, on the order of 70–80%, may be attained in an oscillating flow “with properly designed Wells turbines.”

Operating Principles

Figure 9.25(a) shows a blade in motion at the design speed U in a flow with an upward, absolute axial velocity c_1 . It can be seen that the *relative velocity* w_1 is inclined to the chordline of the blade at an angle α . According to classical aerofoil theory, an *isolated* aerofoil at an angle of incidence α to a free stream will generate a lift force L normal to the direction of the free stream. In a viscous fluid the aerofoil will also experience a drag force D in the direction of the free stream. These lift and drag forces can be resolved into the components of force X and Y as indicated in Figure 9.25(a), i.e.,

$$X = L \cos \alpha + D \sin \alpha, \quad (9.27)$$

$$Y = L \sin \alpha - D \cos \alpha. \quad (9.28)$$

**FIGURE 9.24**

Schematic of a Wells Turbine (Adapted from Raghunathan et al., 1995)

The student should note, in particular, that the force Y acts in the direction of blade motion, giving positive work production.

For a symmetrical aerofoil, the direction of the tangential force Y is the same for both positive and negative values of α , as indicated in Figure 9.25b. If the aerofoils are secured to a rotor drum to form a turbine row, as in Figure 9.24, they will *always* rotate in the direction of the positive tangential force regardless of whether the air is approaching from above or below. With a time-varying, bi-directional air flow the torque produced will fluctuate cyclically but can be smoothed to a large extent by means of a high inertia rotor-generator.

It will be observed from the velocity diagrams that a residual swirl velocity is present for both directions of flow. It was suggested by Raghunathan et al. (1995) that the swirl losses at turbine exit can be reduced by the use of guide vanes.

Two-Dimensional Flow Analysis

The performance of the Wells turbine can be predicted by means of blade element theory. In this analysis the turbine annulus is considered to be made up of a series of concentric elementary rings, each ring being treated separately as a two-dimensional cascade.

The power output from an elementary ring of area $2\pi r dr$ is given by

$$dW = ZU dy,$$

FIGURE 9.25

Velocity and Force Vectors Acting on a Blade of a Wells Turbine in Motion: (a) Upward Absolute Flow onto Blade Moving at Speed U ; (b) Downward Absolute Flow onto Blade Moving at Speed U

where Z is the number of blades and the tangential force on each blade element is

$$dY = C_y \left(\frac{1}{2} \rho w_1^2 l \right) dr.$$

The axial force acting on the blade elements at radius r is $Z dX$, where

$$dX = C_x \left(\frac{1}{2} \rho w_1^2 l \right) dr,$$

and where C_x , C_y are the axial and tangential force coefficients. Now the axial force on all the blade elements at radius r can be equated to the pressure force acting on the elementary ring:

$$2\pi r(p_1 - p_2)dr = ZC_x \left(\frac{1}{2} \rho w_1^2 l \right) dr,$$

so

$$\frac{(p_1 - p_2)}{\frac{1}{2} \rho c_x^2} = \frac{ZC_x l}{2\pi r \sin^2 \alpha_1},$$

where $w_1 = cx/\sin \alpha_1$.

An expression for the efficiency can now be derived from a consideration of all the power losses and the power output. The power lost due to the drag forces is $dW_f = w_1 dD$, where

$$dD = ZC_D \left(\frac{1}{2} \rho w_1^2 l \right) dr$$

and the power lost due to exit kinetic energy is given by

$$dW_k = \left(\frac{1}{2} c_2^2 \right) d\dot{m},$$

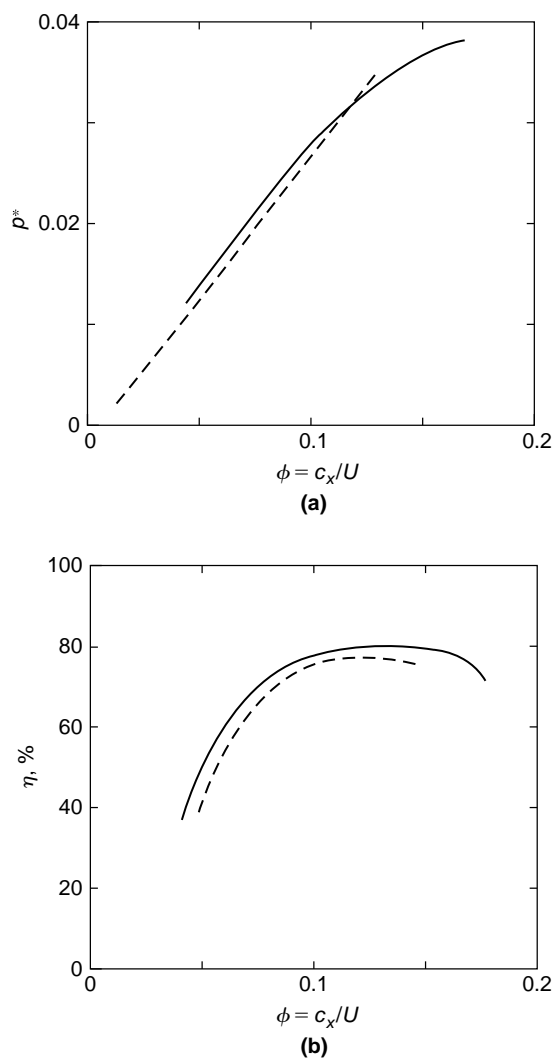

where $d\dot{m} = 2\pi r \rho c_x dr$ and c_2 is the absolute velocity at exit. Thus, the aerodynamic efficiency, defined as power output/power input, can now be written as

$$\eta = \frac{\int_h^t dW}{\int_h^t (dW + dW_f + dW_k)}. \quad (9.29)$$

The predictions for non-dimensional pressure drop p^* and aerodynamic efficiency η determined by Raghunathan et al. (1995) are shown in Figure 9.26(a) and 9.26(b), respectively, together with experimental results for comparison.

Design and Performance Variables

The primary input for the design of a Wells turbine is the air power based upon the pressure amplitude $(p_1 - p_2)$ and the volume flow rate Q at turbine inlet. The performance indicators are the pressure drop, power and efficiency, and their variation with the flow rate. The aerodynamic design and consequent performance is a function of several variables that have been listed by Raghunathan. In non-dimensional form these are

**FIGURE 9.26**

Comparison of Theory with Experiment for the Wells Turbine: — Theory — Experiment (Adapted from Raghunathan, 1995): (a) Non-Dimensional Pressure Drop versus Flow Coefficient; (b) Efficiency versus Flow Coefficient

flow coefficient $\phi = c_x/U$;

solidity at mean radius $\sigma = \frac{2lZ}{\pi D_t(1 + \nu)}$;

hub/tip ratio $\nu = D_h/D_t$;

blade aspect ratio $AR = \text{blade length/chord}$;

blade tip clearance ratio $= t_c/D_t$;

and also blade thickness ratio, turbulence level at inlet to turbine, frequency of waves, and the relative Mach number. It was observed by Raghunathan, Setoguchi, and Kaneko (1987) that the Wells turbine has a characteristic feature that makes it significantly different from most turbomachines: the absolute velocity of the flow is only a (small) fraction of the relative velocity. It is theoretically possible for transonic flow conditions to occur in the relative flow resulting in additional losses due to shock waves and an interaction with the boundary layers leading to flow separation. The effects of these variables on the performance of the Wells turbine have been considered by Raghunathan (1995) and a summary of some of the main findings follow.

Effect of Flow Coefficient

The flow coefficient ϕ is a measure of the angle of incidence of the flow and the aerodynamic forces developed are critically dependent upon this parameter. Typical results based on predictions and experiments of the non-dimensional pressure drop $p^* = \Delta p / (\rho \omega^2 D_t^2)$ and efficiency are shown in Figure 9.26. For a Wells turbine a linear relationship exists between pressure drop and the flow rate [Figure 9.26(a)] and this fact can be employed when making a match between a turbine and an oscillating water column that also has a similar characteristic.

The aerodynamic efficiency η [Figure 9.26(b)] is shown to increase up to a certain value, after which it decreases, because of boundary layer separation.

Effect of Blade Solidity

The solidity is a measure of the blockage offered by the blades to the flow of air and is an important design variable. The pressure drop across the turbine is, clearly, proportional to the axial force acting on the blades. An increase of solidity increases the axial force and likewise the pressure drop. Figure 9.27 shows how the variations of peak efficiency and pressure drop are related to the amount of the solidity.

Raghunathan gives correlations between pressure drop and efficiency with solidity:

$$p^*/p_0^* = 1 - \sigma^2 \text{ and } \eta/\eta_0 = \frac{1}{2}(1 - \sigma^2),$$

where the subscript 0 refers to values for a two-dimensional isolated aerofoil ($\sigma = 0$). A correlation between pressure drop and solidity (for $\sigma > 0$) was also expressed as

$$p^* = A\sigma^{1.6},$$

where A is a constant.

Effect of Hub–Tip Ratio

The hub–tip ratio ν is an important parameter as it controls the volume flow rate through the turbine but also influences the stall conditions, the tip leakage, and, most importantly, the ability of the turbine to run up to operating speed. Values of $\nu < 0.6$ are recommended for design.

**FIGURE 9.27**

Variation of Peak Efficiency and Non-Dimensional Pressure Drop (in Comparison to the Values for an Isolated Aerofoil) versus Solidity: ——— Pressure ——— Efficiency (Adapted from Raghunathan et al., 1995)

The Starting Behaviour of the Wells Turbine

When a Wells turbine is started from rest the incoming relative flow will be at 90° to the rotor blades. According to the choice of the design parameters the blades could be severely stalled and, consequently, the tangential force Y will be small and the acceleration negligible. In fact, if and when this situation occurs the turbine may accelerate only up to a speed much lower than the design operational speed, a phenomenon called *crawling*. The problem can be avoided either by choosing a suitable combination of hub-tip ratio and solidity values at the design stage or by some other means, such as incorporating a starter drive. Values of hub-tip ratio and solidity that have been found to allow self-starting of the Wells turbine are indicated in Figure 9.28.

Pitch-Controlled Blades

Some appreciable improvements have been made in the performance of the Wells turbine as a result of incorporating pitch-controlled blades into the design. The efficiency of the original Wells turbine had a peak of about 80% but the power output was rather low and the starting performance was poor. One reason for the low power output was the low tangential force Y and low flow coefficient ϕ as a consequence of the fixed-blade geometry.

**FIGURE 9.28**

Self-Starting Capability of the Wells Turbine (Adapted from Raghunathan et al., 1995)

A Turbine with Self Pitch-Controlled Blades

Performance enhancement of the Wells turbine reported by Kim et al. (2002) was achieved by incorporating *swivelable vanes* instead of fixed vanes in an experimental test rig. The method they devised used symmetrical blades that pivot about the nose, whose pitch angle changes by a small amount as a result of the varying aerodynamic forces developed by the oscillating flow. This change to the turbine configuration enables a higher torque and efficiency to be obtained from the reciprocating airflow. According to the authors the turbine is geometrically simpler and would be less expensive to manufacture than some earlier methods using “active” pitch-controlled blades, e.g., Sarmiento, Gato, and Falcão (1987) and Salter (1993).

The working principle with self-pitch-controlled blades is illustrated in Figure 9.29. This shows one of the turbine blades fixed to the hub by a pivot located near the leading edge, allowing the blade to move between two prescribed limits, $\pm\gamma$. An aerofoil set at a certain angle of incidence experiences a pitching moment about the pivot, which causes the blade to flip. In this new position the blade develops a higher tangential force and torque at a lower rotational speed than was obtained with the original fixed-blade design of the Wells turbine.

Kim et al., using a piston-driven wind tunnel, measured the performance characteristics of the turbine under steady flow conditions. To determine its running and starting characteristics, a quasi-steady computer simulation of the oscillating through-flow was used together with the steady state characteristics. Details of the turbine rotor are

FIGURE 9.29

Air Turbine Using Self-Pitch-Controlled Blades for Wave Energy Conversion (from Kim et al., 2002, with Permission of Elsevier Science)

Table 9.5 Details of the Turbine Rotor

Blade profile	NACA 0021	Hub-tip ratio	0.7
Blade chord, l	75 mm	Tip diameter	298 mm
Number of blades, Z	8	Hub diameter	208 mm
Solidity	0.75	Blade length, H	45 mm

The turbine characteristics under steady flow conditions were determined in the form of the output torque coefficient C_τ and the input power coefficient C_p against the flow coefficient, $\phi = c_x/U_{av}$, defined as

$$C_\tau = \tau_0 / [\rho(c_x^2 + U_{av}^2)ZlHr_{av}/2], \quad (9.30)$$

$$C_p = \Delta p_0 / [\rho(c_x^2 + U_{av}^2)ZlHr_x/2], \quad (9.31)$$

where τ_0 is the output torque and Δp_0 is the total pressure difference across the turbine.

Figure 9.30(a) shows the C_τ versus ϕ characteristics for the turbine for various blade-setting angles. The solid line ($\gamma = 0^\circ$) represents the result obtained for the original, fixed-blade Wells turbine. For values of $\gamma > 0^\circ$, C_τ decreases with increasing γ in the stall-free zone but, beyond the original stall point for $\gamma = 0$, much higher values of C_τ were obtained.

Figure 9.30(b) shows the C_p versus ϕ characteristics for the turbine for various blade-setting angles. This figure indicates that for $\gamma > 0^\circ$ the input power coefficient C_p is lower than the case where $\gamma = 0^\circ$ for all values of ϕ . Clearly, this is due to the variation in the rotor blade setting angle.

The instantaneous efficiency of the turbine is given by

$$\eta = \frac{\Omega \tau_0}{Q \Delta p_0} = \frac{C_\tau}{\phi C_p} \quad (9.32a)$$

and the mean efficiency over the period of the wave, $T = 1/f$, is

$$\eta_{av} = \left[\frac{1}{T} \int_0^T C_\tau \right] / \left[\frac{1}{T} \int_0^T \phi C_p dt \right]. \quad (9.32b)$$

FIGURE 9.30

Turbine Characteristics under Steady Flow Conditions: (a) Torque Coefficient; (b) Input Power Coefficient (from Kim et al., 2002, with Permission of Elsevier Science)

FIGURE 9.31

Assumed Axial Velocity Variation (from Kim et al., 2002, with Permission of Elsevier Science)

FIGURE 9.32

Mean Efficiency Under Sinusoidally Oscillating Flow Conditions (from Kim et al., 2002, with Permission of Elsevier Science)

Using the measured characteristics for C_T and C_P and assuming a sinusoidal variation of the axial velocity with a different maximum amplitude¹ for each half cycle, as shown in Figure 9.31, the mean efficiency of the cycle can be computed. Figure 9.32 shows the mean efficiency as a function of the flow coefficient ϕ for a range of γ values with $c_{xi} = 0.6c_{xo}$.

¹Kim et al. reported a lower maximum axial velocity c_{xi} during inhalation than exhalation c_{xo} .

Compared to the basic Wells turbine (with $\gamma = 0^\circ$), the optimum result for $\gamma = 10^\circ$ shows an improved mean efficiency and an optimum flow coefficient of about 0.4. It is apparent that further field testing would be needed to prove the concept.

Further Work

Energetech in Sydney, Australia, began (circa. 2003) the design of a half-scale test turbine, which will be used for more detailed flow studies and to test new blade–hub arrangements. Also, a full-scale 1.6 m diameter variable-pitch turbine has been constructed for use at the prototype wave energy plant at Port Kembla, New South Wales, Australia. Studies of derivatives of the Wells turbine are also being undertaken at research centres in the United Kingdom, Ireland, Japan, India, and other countries. It is still not clear which type of blading or which pitch-control system will prevail. Kim et al. (2001) attempted a comparison of five derivatives of the Wells turbine using steady flow data and numerical simulation of an irregular wave motion. However, at present a “best” type has still not emerged from a welter of data. A final conclusion must await the outcome of further development and the testing of prototypes subjected to real sea wave conditions.

9.11 TIDAL POWER

Tidal energy is generated by the relative motion of the Earth, Sun, and Moon system whose gravitational forces cause periodic changes to the water levels on the Earth’s surface. The magnitude of the tide at any given location is the result of the varying positions of the Moon and Sun relative to that of the Earth, the rotation of the Earth, the shape of the sea bed, and the magnifying effects of the coast. The Moon is the main cause of these tides and the Sun to a much lesser extent. When the Sun and Moon are in-line with the Earth (Figure 9.33) the gravitational force is greatest causing bigger tides (so-called spring tides).

With the Sun and Moon disposed at 90° to the Earth the gravitational pull on the Earth is weakest (the so-called neap tide). It is worth noting that tidal power is inexhaustible for all practical purposes (it is a *renewable energy resource*).² At any one moment in time there are two high tides and two low tides around the Earth. One high tide occurs on the longitude closest to the Moon and the other on the longitude furthest from it. Of course, at the same time the low tides are occurring at longitudes that are at 90° to those at which the high tides are occurring. The interval between high tide is about 12 hours 25 minutes. The *tidal range* is the difference in height between high and low tides. In mid-ocean the tidal range is between 0.5 and 1.0 metres but in the coastal regions the range can be significantly enhanced. In the Severn estuary (United Kingdom) the tidal range can be as much as 14 m and other shallow areas, e.g., the Bay of Fundy (Nova Scotia), the tidal range can exceed 13 m. Other coastal regions have enhanced tidal ranges and many are under consideration for the installation of tidal energy generators.

²Williams (2000) records that tidal activity has caused a loss of mechanical energy in the Earth–Moon system due to pumping of water through natural restrictions around coastlines, to viscous dissipation at the seabed, and in turbulence. Over the last 620 million years this loss of energy is estimated to have caused the Earth’s speed of rotation to slow down, the period of rotation is estimated to have increased from 21.9 hours to the present 24 hours. Energy taken from the tides by humankind would be insignificant on a world-scale and would have a negligible effect on the Earth’s rotation.

**FIGURE 9.33**

Sun, Moon, and Earth Orientations Causing Spring and Neap Tides

Several of these tidal generators have been installed for long-term evaluations and testing and recent commercial enterprises have produced successful results. Compared to wind and solar energy, tidal power has the great advantage of being entirely predictable.

Categories of Tidal Power

There are two main types of tidal power generator:

- (i) tidal stream systems that use the kinetic energy of the water to power turbines;
- (ii) barrages that make use of the potential energy of the water trapped between high and low tides.

Barrages are essentially dams stretching across the full width of a tidal estuary. Because of their very high civil engineering construction costs, environmental problems they can cause, and also a world-wide lack of suitable sites (they require a minimum tidal range of at least 7 m for economic reasons) very few are likely to be made. The *La Rance scheme* in France, however, has been in operation since 1966. It was the first tidal barrage in the world, took six years to build, and provides an output of 240 MW. This type of tidal power generator is not considered any further.

Tidal Stream Generators

This is a relatively new technology and is still under development. It appears that the most successful approach is based on axial turbine practice. Since April 2007 Verdant Power has been running a demonstration project in the East River between Queens and Roosevelt Island in New York City. It is noted that the strength of the currents at that location have posed serious engineering

challenges: the blades of the 2006 and 2007 prototypes broke off. Because of the robust underwater environment they encounter, new stronger blades were installed in September 2008. Several other installations based on the axial turbine design have been tried out at Kvalsund in Norway (300 kW) in 2003 and the SeaGen project at Strangford Lough in Northern Ireland has proved successful and has been providing 1.2 MW to the grid.

The SeaGen Tidal Turbine

Strangford Lough is a large (150 km²) shallow lagoon situated on the east coast of Northern Ireland, open to the sea. The entrance to the lough is a deep channel (the Narrows) about 8 km long and about 0.5 km wide. The currents through the Narrows are extremely strong and fast, reaching up to about 4 m/s at full flow.

At present little technical information has been released by the manufacturers (Marine Current Turbines, Ltd.) about the SeaGen project but, using the data given and with the aid of actuator disc theory as applied to wind turbines (Chapter 10), some of the leading values of the operating parameters can be estimated. The background to the design philosophy, development and testing of the pioneering “Sea-flow Project,” which preceded SeaGen, and the preparation for the installation of SeaGen itself is described by Fraenkel (2007).

Figure 9.34 shows the structural arrangement of SeaGen comprising two unshrouded axial flow turbines, 16 m tip diameter, supported on a single beam. At the design speed, given as 14 rpm, each turbine provides 600 kW. The configuration of the turbines appears to be the same as that of horizontal axis wind turbines studied in Chapter 10. The rotor blades can be pitched through 180° to allow operation of the turbine on both the ebb and flood tides.

From the actuator disc theory used in Chapter 10, eqn. (10.15b), the turbine *hydrodynamic power output* is

$$P = \frac{1}{2} \rho A C_p c_{x1}^3,$$

where A is the blade disc area, C_p is the power coefficient, ρ is the density of sea-water, and c_{x1} is the velocity of the water approaching the turbine.

EXAMPLE 9.7

Determine the minimum flow speed of the water approaching the SeaGen tidal turbine in order for the full design power of 600 kW (for each turbine) to be achieved and also the blade tip-speed ratio. Assume the power coefficient $C_p = 0.3$,³ the blade diameter is 16 m, and the density of sea-water is 1025 kg/m³.

Solution

From the preceding equation,

$$c_{x1}^3 = P / \left(\frac{1}{2} \rho A C_p \right) = P / \left(\frac{\pi}{8} \rho D^2 C_p \right) = \frac{600 \times 10^3}{\frac{\pi}{8} \times 1025 \times 16^2 \times 0.3} = 19.41.$$

³Values of C_p for horizontal axis wind turbines are normally found in the range 0.3 to 0.35. The Betz limit for C_p is 0.593.

**FIGURE 9.34**

SeaGen Tidal Power Generator (With Permission of Marine Current Turbines, Ltd.)

Therefore,

$$c_{x1} = 2.69 \text{ m/s.}$$

The blade tip speed is

$$U_t = \Omega r_t = \left(\frac{14}{30} \pi \right) \times 8 = 11.73 \text{ m/s.}$$

Hence, the blade tip-speed ratio (when full power is reached) is,

$$J = \frac{U_t}{c_{x1}} = \frac{11.73}{2.69} = 4.36.$$

This value of blade tip-speed ratio conforms with the values found for horizontal axis wind turbines (HAWTs).

PROBLEMS

1. A generator is driven by a small, single-jet Pelton turbine designed to have a power specific speed $\Omega_{sp} = 0.20$. The effective head at nozzle inlet is 120 m and the nozzle velocity coefficient is 0.985. The runner rotates at 880 rev/min, the turbine overall efficiency is 88%, and the mechanical efficiency is 96%. If the blade speed–jet speed ratio, $v = 0.47$, determine

- (i) the shaft power output of the turbine;
 - (ii) the volume flow rate;
 - (iii) the ratio of the wheel diameter to jet diameter.
2. (a) Water is to be supplied to the Pelton wheel of a hydroelectric power plant by a pipe of uniform diameter, 400 m long, from a reservoir whose surface is 200 m vertically above the nozzles. The required volume flow of water to the Pelton wheel is $30 \text{ m}^3/\text{s}$. If the pipe skin friction loss is not to exceed 10% of the available head and $f = 0.0075$, determine the minimum pipe diameter.
- (b) You are required to select a suitable pipe diameter from the available range of stock sizes to satisfy the criteria given. The range of diameters (m) available are 1.6, 1.8, 2.0, 2.2, 2.4, 2.6, and 2.8. For the diameter you have selected, determine
- (i) the friction head loss in the pipe;
 - (ii) the nozzle exit velocity assuming no friction losses occur in the nozzle and the water leaves the nozzle at atmospheric pressure;
 - (iii) the total power developed by the turbine assuming that its efficiency is 75% based upon the energy available at turbine inlet.
3. A multi-jet Pelton turbine with a wheel 1.47 m diameter, operates under an effective head of 200 m at nozzle inlet and uses $4 \text{ m}^3/\text{s}$ of water. Tests have proved that the wheel efficiency is 88% and the velocity coefficient of each nozzle is 0.99. Assuming that the turbine operates at a blade speed to jet speed ratio of 0.47, determine
- (i) the wheel rotational speed;
 - (ii) the power output and the power specific speed;
 - (iii) the bucket friction coefficient given that the relative flow is deflected 165° ;
 - (iv) the required number of nozzles if the ratio of the jet diameter–mean diameter of the wheel is limited to a maximum value of 0.113.
4. A four-jet Pelton turbine is supplied by a reservoir whose surface is at an elevation of 500 m above the nozzles of the turbine. The water flows through a single pipe 600 m long, 0.75 m diameter, with a friction coefficient $f = 0.0075$. Each nozzle provides a jet 75 mm diameter and the nozzle velocity coefficient $K_N = 0.98$. The jets impinge on the buckets of the wheel at a radius of 0.65 m and are deflected (relative to the wheel) through an angle of 160° . Fluid friction within the buckets reduces the relative velocity by 15%. The blade speed–jet speed ratio $v = 0.48$ and the mechanical efficiency of the turbine is 98%. Calculate, using an iterative process, the loss of head in the pipeline and, hence, determine for the turbine
- (i) the speed of rotation;
 - (ii) the overall efficiency (based on the effective head);
 - (iii) the power output;
 - (iv) the percentage of the energy available at turbine inlet that is lost as kinetic energy at turbine exit.
5. A Francis turbine operates at its maximum efficiency point at $\eta_0 = 0.94$, corresponding to a power specific speed of 0.9 rad. The effective head across the turbine is 160 m and the speed required for electrical generation is 750 rev/min. The runner tip speed is 0.7 times the spouting

velocity, the absolute flow angle at runner entry is 72° from the radial direction, and the absolute flow at runner exit is without swirl. Assuming there are no losses in the guide vanes and the mechanical efficiency is 100%, determine

- (i) the turbine power and the volume flow rate;
 - (ii) the runner diameter;
 - (iii) the magnitude of the tangential component of the absolute velocity at runner inlet;
 - (iv) the axial length of the runner vanes at inlet.
6. The power specific speed of a 4 MW Francis turbine is 0.8, and the hydraulic efficiency can be assumed to be 90%. The head of water supplied to the turbine is 100 m. The runner vanes are radial at inlet and their internal diameter is three quarters of the external diameter. The meridional velocities at runner inlet and outlet are equal to 25 and 30%, respectively, of the spouting velocity. Determine
- (i) the rotational speed and diameter of the runner;
 - (ii) the flow angles at outlet from the guide vanes and at runner exit;
 - (iii) the widths of the runner at inlet and at exit.

Blade thickness effects can be neglected.

7. (a) Review, briefly, the phenomenon of cavitation in hydraulic turbines and indicate the places where it is likely to occur. Describe the possible effects it can have upon turbine operation and the turbine's structural integrity. What strategies can be adopted to alleviate the onset of cavitation?
- (b) A Francis turbine is to be designed to produce 27 MW at a shaft speed of 94 rev/min under an effective head of 27.8 m. Assuming that the optimum hydraulic efficiency is 92% and the runner tip speed–jet speed ratio is 0.69, determine
- (i) the power specific speed;
 - (ii) the volume flow rate;
 - (iii) the impeller diameter and blade tip speed.
- (c) A 1/10 scale model is to be constructed to verify the performance targets of the prototype turbine and to determine its cavitation limits. The head of water available for the model tests is 5.0 m. When tested under dynamically similar conditions as the prototype, the net positive suction head H_S of the model is 1.35 m. Determine for the model
- (i) the speed and the volume flow rate;
 - (ii) the power output, corrected using Moody's equation to allow for scale effects (assume a value for $n = 0.2$);
 - (iii) the suction specific speed Ω_{SS} .
- (d) The prototype turbine operates in water at 30°C when the barometric pressure is 95 kPa. Determine the necessary depth of submergence of that part of the turbine most likely to be prone to cavitation.
8. The preliminary design of a turbine for a new hydroelectric power scheme has under consideration a vertical-shaft Francis turbine with a hydraulic power output of 200 MW under an effective

head of 110 m. For this particular design a specific speed, $\Omega_s = 0.9$ (rad), is selected for optimum efficiency. At runner inlet the ratio of the absolute velocity to the spouting velocity is 0.77, the absolute flow angle is 68° , and the ratio of the blade speed to the spouting velocity is 0.6583. At runner outlet the absolute flow is to be without swirl. Determine

- (i) the hydraulic efficiency of the rotor;
 - (ii) the rotational speed and diameter of the rotor;
 - (iii) the volume flow rate of water;
 - (iv) the axial length of the vanes at inlet.
9. A Kaplan turbine designed with a *shape factor* (power specific speed) of 3.0 (rad), a runner tip diameter of 4.4 m, and a hub diameter of 2.0 m, operates with a net head of 20 m and a shaft speed of 150 rev/min. The absolute flow at runner exit is axial. Assuming that the hydraulic efficiency is 90% and the mechanical efficiency is 99%, determine
- (i) the volume flow rate and shaft power output;
 - (ii) the relative flow angles at the runner inlet and outlet at the hub, at the mean radius and at the tip.
10. A hydroelectric power station is required to generate a total of 4.2 MW from a number of single-jet Pelton wheel turbines each operating at the same rotational speed of 650 rpm, at the same power output and at a power specific speed of 1.0 rev. The nozzle efficiency η_N of each turbine can be assumed to be 0.98, the overall efficiency η_o is assumed to be 0.88, and the blades speed to jet speed ratio v is to be 0.47. If the effective head H_E at the entry to the nozzles is 250 m, determine
- (i) the number of turbines required (round up the value obtained);
 - (ii) the wheel diameter;
 - (iii) the total flow rate.
11. (a) In the previous problem the reservoir surface is 300 m above the turbine nozzles and the water is supplied to the turbines by three pipelines, each 2 km long and of constant diameter. Using Darcy's formula determine a suitable diameter for the pipes assuming the friction factor $f = 0.006$.
- (b) The chief designer of the scheme decides that a *single pipeline* would be more economical and that its cross-sectional area would need to be equal to the total cross-sectional area of the pipelines in the previous scheme. Determine the resulting friction head loss assuming that the friction factor remains the same and that the total flow rate is unchanged.
12. Sulzer Hydro Ltd. of Zurich at one time manufactured a six-jet vertical shaft Pelton wheel turbine with a power rating of 174.4 MW, with a runner diameter of 4.1 m, and an operating speed of 300 rev/min with an effective head of 587 m. Assuming the overall efficiency is 0.90 and the nozzle efficiency is 0.99, determine
- (i) the power specific speed;
 - (ii) the blade speed–jet speed ratio;
 - (iii) the volume flow rate.

Considering the values shown in Figure 9.2, comment on your result.

13. A vertical axis Francis turbine has a runner diameter of 0.825 m, operates with an effective head, $H_E = 6.0$ m, and produces 200 kW at the shaft. The rotational speed of the runner is 250 rpm, the overall efficiency is 0.90, and the hydraulic efficiency is 0.96. If the meridional (i.e., flow) velocity of the water through the runner is constant and equal to $0.4\sqrt{2gH_E}$ and the exit absolute flow is without swirl, determine the vane exit angle, the inlet angle of the runner vanes, and the runner height at inlet. Evaluate the power specific speed of the turbine and decide if the data given is consistent with the stated overall efficiency.
14. (a) A prototype Francis turbine is to be designed to operate at 375 rpm^4 at a power specific speed of 0.8 (rad), with an effective head of 25 m. Assuming the overall efficiency is 92%, the mechanical efficiency is 99%, the runner tip speed to jet speed ratio is 0.68, and the flow at runner exit has zero swirl, determine
- (i) the shaft power developed;
 - (ii) the volume flow rate;
 - (iii) the impeller diameter and blade tip speed;
 - (iv) the absolute and relative flow angles at runner inlet if the meridional velocity is constant and equal to 7.0 m/s.
- (b) Using Thoma's coefficient and the data in Figure 9.21, investigate whether the turbine is likely to experience cavitation. The vertical distance between the runner and the tailrace is 2.5 m, the atmospheric pressure is 1.0 bar, and the water temperature is 20°C.
15. For the previous problem a 1/5 scale model turbine of the prototype is to be made and tested to check that the performance targets are valid. The test facility has an available head of 3 m. For the model, determine
- (i) the rotational speed and volume flow rate;
 - (ii) the power developed (uncorrected for scale).
16. A radial flow hydraulic turbine whose design is based on a power specific speed, $\Omega_{sp} = 1.707$ is to produce 25 MW from a total head, $H_E = 25$ m. The overall turbine efficiency $\eta_o = 0.92$, the mechanical efficiency is 0.985, and the loss in head in the nozzles is 0.5 m. The ratio of the blade tip speed to jet speed is 0.90. Assuming the meridional velocity is constant and equal to 10 m/s and there is no swirl in the runner exit flow, determine
- (i) the volume flow rate through the turbine;
 - (ii) the rotational speed and diameter of the runner;
 - (iii) the absolute and relative flow angles at entry to the runner.
17. An axial flow hydraulic turbine operates with a head of 20 m at turbine entry and develops 10 MW when running at 250 rev/min. The blade tip diameter is 3 m, the hub diameter is 1.25 m, and the runner design is based upon a "free vortex." Assuming the hydraulic efficiency is 94%, the overall efficiency is 92%, and the flow at exit is entirely axial, determine the absolute and relative flow angles upstream of the runner at the hub, mean, and tip radii.

⁴This speed is suitable for synchronous generation at 50 cycles per second.

18. (a) A model of a Kaplan turbine, built to a scale of 1/6 of the full-scale prototype, develops an output of 5 kW from a net head of 1.2 m of water at a rotational speed of 300 rev/min and a flow rate of 0.5 m³/s. Determine the efficiency of the model.
- (b) By using the scaling laws estimate the rotational speed, flow rate, and power of the prototype turbine when running with a net head of 30 m.
- (c) Determine the power specific speed for both the model and for the prototype, corrected with Moody's equation. To take account of the effects of size (scale) use the Moody formula

$$(1 - \eta_p) = (1 - \eta_m)(D_m/D_p)^{0.25}$$

to estimate the full-scale efficiency, η_p , and the corresponding power.

Wind Turbines

10

Take care your worship, those things over there are not giants but windmills.

M. Cervantes, *Don Quixote*, Part 1, Chapter 8

10.1 INTRODUCTION

Wind power comes from the conversion of wind energy into electricity using wind turbines to drive the electrical generators. Over the past three decades there has been a remarkable growth in global installed generating capacity. The data given in Figure 10.1 obtained from statistics published by the *Global Wind Energy Council* (GWEC), the *European Wind Energy Association* (EWEA), the *American Wind Energy Association* (AWEA), and others showing the regional and worldwide growth of installed wind power capacity. It is interesting to note that the global wind power capacity is now doubling every three years. The biggest regional contributors to this growth are Europe (particularly Germany and Spain) and the United States. Up to May 2009, 80 countries around the world contributed to the generation of wind power on a commercial scale. Predicting the growth of wind power generation is far from reliable. At the end of 2008 the total worldwide wind power capacity had reached 121 GW. The prediction by the German Wind Energy Association in March 2004 that the global market for wind power could reach 150 GW by 2012 turns out to be too pessimistic. This can be shown as follows, based upon the *exponential law of growth*:

$$P = P_0 \exp(kt),$$

where P_0 is the initial installed power = 121 GW and P is the predicted installed power = 150 GW. We can determine the amount of time t needed to reach the predicted installed power if we know the value of the constant k . As the rate of doubling, previously stated, $k = 3$ years, $\ln(2) = k \times 3$, so $k = \ln(2)/3 = 0.231$. Thus,

$$P/P_0 = 150/121 = \exp(0.231t).$$

Therefore, $t = 0.93$ years. So, we should have passed that goal already (November 2009)!

Wind Energy Availability

The Earth receives more energy from the Sun at the equator than at the poles. Dry land heats up (and cools down) more quickly than the oceans. This differential heating and cooling, which is greatest near the equator, drives an atmospheric convection system extending from sea level to the upper

**FIGURE 10.1**

Operational Wind Power Capacity

atmosphere. The warm air rises, circulates in the atmosphere, and gradually sinks back to the surface in the cooler regions. At the upper levels of the atmosphere, continuous wind speeds are known to exceed 150 km/h. The large scale motion of the air at altitude causes a circulation pattern with well-known features at sea level such as the trade winds.

The most striking characteristic of wind energy is its variability both spatially and temporally. This variability depends on many factors: climatic region, topography, season of the year, altitude, type of local vegetation, etc. Topography and altitude have a major influence on wind strength. The strength of wind on the high ground and mountain tops is greater than in the sheltered valleys. Coastal regions are often more windy than further inland because of the difference in heating between land and sea. On the other hand the presence of vegetation and its density is a factor that usually lessens wind strength.

At any given location temporal variability can mean that the amount of wind strength can change from one year to the next. The cause of these changes are not well understood but may be generated by large scale variations in weather systems and ocean currents.

The proper design and size of a wind turbine will depend crucially upon the site under consideration having a favourable wind. Briefly, to be *favourable*, the wind would need to be of sufficient strength and duration at an acceptable height. For the locations being considered as possible sites extended anemometric surveys (lasting over at least a year) are needed to determine the nature of the wind speed distribution with respect to time and height above the ground. These surveys are generally carried out at a fairly standard height of 30 m above the ground and, when required, some sort of extrapolation is made for estimating wind speeds at other heights. To assess the frequency of the

occurrence of wind speeds at a site, a probability distribution function is often employed to fit the observed data. Several types of these distribution functions are commonly used:

- (i) the simple, but less accurate, single-parameter *Rayleigh distribution*;
- (ii) the complicated but more accurate, two-parameter *Weibull distribution*.

Some further details of these distributions and their application are given by Burton et al. (2001).

From these data, estimates of power output for a range of turbine designs and sizes can be made. Wind turbine rotors have been known to suffer damage or even destruction from excessive wind speeds and obviously this aspect requires very careful consideration of the worst case wind conditions so the problem may be avoided.

An important issue concerning the installation of wind power plants involves their environmental impact. Walker and Jenkins (1997) have outlined the most significant benefits for installing wind turbines as well as the reasons put forward to counter their installation. It is clear that the benefits include the reduction in the use of fossil fuels, leading to a reduction in the emission of pollutants (the most important of these being the oxides of carbon, sulphur, and nitrogen). Any emissions caused by the manufacture of the wind turbine plant itself are offset after a few months of emission-free operation. Similarly, the energy expended in the manufacture of a wind turbine, according to the World Energy Council (1994), is paid back after about a year's normal productive operation.

Historical Viewpoint

It may be of interest to mention a little about how the modern wind turbine evolved. Of course, the extraction of mechanical power from the wind is an ancient practice dating back at least 3000 years. Beginning with sailing ships the technical insight gained from them was extended to the early windmills for the grinding of corn etc. Windmills are believed to have originated in Persia in the seventh century and their use had spread across Europe by the twelfth century. The design was gradually improved, especially in England during the eighteenth century where millwrights developed remarkably effective self-acting control mechanisms. A brick built tower windmill, Figure 10.2, a classic version of this type, still exists on Bidston Hill¹ near Liverpool, United Kingdom, and was used to grind corn into flour for 75 years up until 1875. It has now become a popular historical attraction.

The wind pump was first developed in Holland for drainage purposes while, in the United States the deep-well pump was evolved for raising water for stock watering. Most windmills employ a rotor with a near horizontal axis, the sails were originally of canvas, a type still in use today in Crete. The English windmill employed wooden sails with pivoted slats for control. The U.S. wind-pump made use of a large number of sheet-metal sails (Lynette and Gipe, 1998). The remarkable revival of interest in modern wind powered machines appears to have started in the 1970s because of the so-called fuel crisis. A most interesting brief history of wind turbine design is given by Eggleston and Stoddard (1987). Their focus of attention was the use of wind power for generating electrical energy rather than mechanical energy. A rather more detailed history of the engineering development of windmills from the earliest times leading to the introduction of the first wind turbines is given by Shepherd (1998).

¹It is situated within 1 km of the Liverpool author's home.

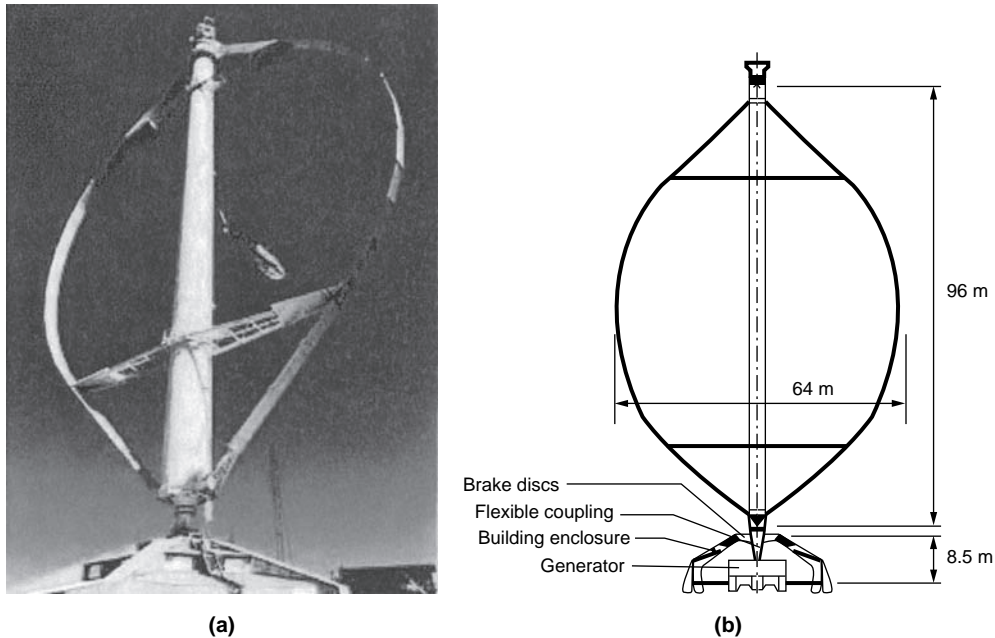

**FIGURE 10.2**

10.2 TYPES OF WIND TURBINE

Wind turbines fall into two main categories, those that depend upon aerodynamic drag to drive them (i.e., the old style windmills) and those that depend upon aerodynamic lift. Drag machines such as those developed in ancient times by the Persians were of very low efficiency compared with modern turbines (employing lift forces) and so are not considered any further in this chapter.

The design of the modern wind turbine is based upon aerodynamic principles, which are elaborated later in this chapter. The rotor blades are designed to interact with the oncoming airflow so that an aerodynamic lift force is developed. A drag force is also developed but, in the normal range of pre-stall

**FIGURE 10.3**

(a) The 4 MW Eolè VAWT Installed at Cap-Chat, Quebec; (b) Sketch of VAWT Eolè Showing the Major Components, Including the Direct-Drive Generator (Courtesy AWEA)

operation, this will amount to only about 1 or 2% of the lift force. The lift force, and the consequent positive torque produced, drives the turbine thereby developing output power.

In this chapter, the focus of attention is necessarily restricted to the aerodynamic analysis of the *horizontal axis wind turbine* (HAWT) although some mention is given of the *vertical axis wind turbine* (VAWT). The VAWT, also referred to as the *Darrieus turbine* after its French inventor in the 1920s, uses vertical and often slightly curved symmetrical aerofoils. Figure 10.3(a) shows a general view of the very large 4.2 MW vertical axis Darrieus wind turbine called the *Eolè* VAWT installed at Cap-Chat, Quebec, Canada, having an effective diameter of 64 m and a blade height of 96 m.

Figure 10.3(b), from Richards (1987), is a sketch of the major components of this aptly named *egg-beater* wind turbine. Guy cables (not shown) are required to maintain the turbine erect. This type of machine has one distinct advantage: it can operate consistently without regard to wind direction. However, it does have a number of major disadvantages:

- (i) wind speeds are low close to the ground so that the lower part of the rotor is rather less productive than the upper part;
- (ii) high fluctuations in torque occur with every revolution;
- (iii) negligible self-start capability;
- (iv) limited capacity for speed regulation in winds of high speed.

Darrieus turbines usually require mechanical power input to start them but have been known to self-start. (Several VAWTs have been destroyed by such self-starts.) For assisted starting the method used is to run the generator as a motor up to a speed when aerodynamic wind forces can take over. Stopping a VAWT in high winds is difficult as aerodynamic braking has not been successful and friction braking is needed.

According to Ackermann and Söder (2002), VAWTs were developed and produced commercially in the 1970s until the 1980s. Since the end of the 1980s research and development on VAWTs has virtually ceased in most countries, apart from Canada (see Gasch, 2002; Walker and Jenkins, 1997; and Divone, 1998).

Large HAWTs

The HAWT type is currently dominant in all large scale applications for extracting power from the wind and seems likely to remain so. The large HAWT, Figure 10.4(a), operating at Barrax, Spain, is 104 m in

FIGURE 10.4

(a) First General Electric Baseline HAWT, 3.6 MW, 104 m Diameter, Operating at Barrax, Spain, Since 2002. (Courtesy U.S. Department of Energy). (b) The Bergey Excel-S, Three-Bladed, 7 m Diameter Wind Turbine, Rated at 10 kW at Wind Speed of 13 m/s (With Permission of Bergey Windpower Company)

diameter and can generate 3.6 MW. (This size of wind turbine has now, in 2010, become fairly commonplace, especially in the coastal waters around Great Britain.) Basically, a HAWT comprises a nacelle mounted on top of a high tower, containing a generator and, usually, a gearbox to which the rotor is attached. Increasing numbers of wind turbines do not have gearboxes but use a direct drive. A powered *yaw system* is used to turn the turbine so that it faces into the wind. Sensors monitor the wind direction and the nacelle is turned according to some integrated average wind direction. The number of rotor blades employed depends on the purpose of the wind turbine. As a rule, three-bladed rotors are used for the generation of electricity. Wind turbines with only two or three blades have a high ratio of blade tip speed to axial flow velocity (the tip-speed ratio), but only a low starting torque and may even require assistance at startup to bring it into the useful power producing range of operation. Commercial turbines range in capacity from a few hundred kilowatts to more than 3 MW. The crucial parameter is the diameter of the rotor blades, the longer the blades, the greater is the “swept” area and the greater the possible power output. Rotor diameters now range to over 100 m. The trend has been towards larger machines as they can produce electricity at a lower price. Most wind turbines of European origin are made to operate upwind of the tower, i.e., they face into the wind with the nacelle and tower downstream. However, there are also wind turbines of downwind design, where the wind passes the tower before reaching the rotor blades. Advantages of the upwind design are that there is little or no tower “shadow” effect and lower noise level than the downwind design.

Small HAWTs

Small wind turbines with a horizontal axis were developed in the nineteenth century for mechanical pumping of water, e.g., the American farm pump. The rotors had 20 or more blades, a low tip-speed ratio but a high starting torque. With increasing wind speed pumping would then start automatically. According to Baker (1985), the outgrowth of the utility grid caused the decline of the wind driven pump in the 1930s. However, there has been a worldwide revival of interest in small HAWTs of modern design for providing electricity in remote homes and isolated communities that are “off grid.” The power output of such a wind powered unit would range from about 1 to 50 kW. Figure 10.4(b) shows the Bergey Excel-S, which is a three-blade upwind turbine rated at 10 kW at a wind speed of 13 m/s. This is currently America’s most popular residential and small business wind turbine.

Tower Height

An important factor in the design of HAWTs is the tower height. The wind speed is higher the greater the height above the ground. This is the meteorological phenomenon known as *wind shear*. This common characteristic of wind can be used to advantage by employing wind towers with increased hub heights to capture more wind energy. A study by Livingston and Anderson (2004) investigated the wind velocities at heights up to 125 m on the Great Plains (United States) and provide a compelling case for operating wind turbines with hub heights of at least 80 m. Typically, in daytime the variation follows the wind profile one-seventh power law (i.e., wind speed increases proportionally to the seventh root of height above the surface):

$$c_x/c_{x,\text{ref}} = (h/h_{\text{ref}})^n,$$

where c_x is the wind speed at height h , $c_{x,\text{ref}}$ is the known wind speed at a reference height h_{ref} . The exponent n is an empirically derived coefficient. In a neutrally stable atmosphere and over open ground (the normal

condition), $n \approx 1/7$ or 0.143. Over open water a more appropriate coefficient is $n \approx 0.11$. As an example it is required to estimate the wind speed at a height of 80 m above the ground using a reference velocity of 15 m/s measured at a height of 50 m:

$$c_x = 15(80/50)^{0.143} = 16.04 \text{ m/s.}$$

Even small increases in wind speed can be important. It is shown later that the power extracted from the wind varies as the cube of the wind speed. Using this example the increase in the power extracted would be over 22% as a result of increasing the hub height from 50 m to 80 m. Of course there is a penalty as costs are likely to be greater for the stronger tower structure required.

Storing Energy

Because of the intermittency of wind and the unavailability at times of the required energy it is often claimed by opponents of wind turbines that it is better to rely on other sources of power. Clearly, some form of energy storage can be devised. In Spain, more than 13.8 GW of wind power capacity has been installed, providing about 10% of that country's electricity needs, according to *Renewable Energy World* (September–October, 2009). At *Iberdrola, Spain*, a pumped storage scheme (852 MW) is now being used to store the excess wind turbine energy and three further pumped storage plants are likely to be built with a total capacity of 1.64 GW.

10.3 OUTLINE OF THE THEORY

In the following pages the aerodynamic theory of the HAWT is gradually developed, starting with the simple one-dimensional momentum analysis of the actuator disc and followed by the more detailed analysis of the blade element theory. The flow state just upstream of the rotor plane forms the so-called inflow condition for the rotor blades and from which the aerodynamic forces acting on the blades can be determined. The well-known blade element momentum (BEM) method is outlined and used extensively. A number of worked examples are included at each stage of development to illustrate the application of the theory. Detailed calculations using the BEM method were made to show the influence of various factors, such as the tip-speed ratio and blade number on performance. Further development of the theory includes the application of Prandtl's tip loss correction factor, which corrects for a finite number of blades. Glauert's optimisation analysis is developed and used to determine the ideal blade shape for a given lift coefficient and to show how the optimum rotor power coefficient is influenced by the choice of tip-speed ratio.

10.4 ACTUATOR DISC APPROACH

Introduction

The concept of the actuator disc was used in Chapter 6 as a method of determining the three-dimensional flows in compressor and turbine blade rows. Betz (1926) in his seminal work on the flow through windmill blades used a much simpler version of the actuator disc. As a start to understanding the power production process of the turbine consider the flow model shown in Figure 10.5 where the rotor of the

**FIGURE 10.5**

Actuator Disc and Boundary Stream Tube Model

HAWT is replaced by an actuator disc. It is necessary to make a number of simplifying assumptions concerning the flow but, fortunately, the analysis yields useful approximate results.

Theory of the Actuator Disc

The following assumptions are made:

- (i) steady uniform flow upstream of the disc;
- (ii) uniform and steady velocity at the disc;
- (iii) no flow rotation produced by the disc;
- (iv) the flow passing through the disc is contained both upstream and downstream by the boundary stream tube;
- (v) the flow is incompressible.

Because the actuator disc offers a resistance to the flow the velocity of the air is reduced as it approaches the disc and there will be a corresponding increase in pressure. The flow crossing through the disc experiences a sudden drop in pressure below the ambient pressure. This discontinuity in pressure at the disc characterises the actuator. Downstream of the disc there is a gradual recovery of the pressure to the ambient value.

We define the axial velocities of the flow far upstream ($x \rightarrow -\infty$), at the disc ($x = 0$) and far downstream ($x \rightarrow \infty$) as c_{x1} , c_{x2} and c_{x3} , respectively. From the continuity equation the mass flow is

$$\dot{m} = \rho c_{x2} A_2, \quad (10.1)$$

where ρ = air density and A_2 = area of disc.

The axial force acting on the disc is

$$X = \dot{m}(c_{x1} - c_{x3}) \quad (10.2)$$

and the corresponding power extracted by the turbine or actuator disc is

$$P = X c_{x2} = \dot{m}(c_{x1} - c_{x3}) c_{x2}. \quad (10.3)$$

The rate of energy loss by the wind must then be

$$P_W = \dot{m}(c_{x1}^2 - c_{x3}^2)/2. \quad (10.4)$$

Assuming no other energy losses, we can equate the power lost by the wind to the power gained by the turbine rotor or actuator:

$$P_W = P,$$

$$\dot{m}(c_{x1}^2 - c_{x3}^2)/2 = \dot{m}(c_{x1} - c_{x3})c_{x2},$$

therefore,

$$c_{x2} = \frac{1}{2}(c_{x1} + c_{x3}). \quad (10.5)$$

This is the proof developed by Betz (1926) to show that the velocity of the flow in the plane of the actuator disc is the mean of the velocities far upstream and far downstream of the disc. We should emphasise again that wake mixing, which must physically occur far downstream of the disc, has so far been ignored.

An Alternative Proof of Betz's Result

The air passing across the disc undergoes an overall change in velocity ($c_{x1} - c_{x3}$) and a corresponding rate of change of momentum equal to the mass flow rate multiplied by this velocity change. The force causing this momentum change is equal to the difference in pressure across the disc times the area of the disc. Thus,

$$\begin{aligned} (p_{2+} - p_{2-})A_2 &= \dot{m}(c_{x1} - c_{x3}) = \rho A_2 c_{x2}(c_{x1} - c_{x3}), \\ \Delta p &= (p_{2+} - p_{2-}) = \rho c_{x2}(c_{x1} - c_{x3}) \end{aligned} \quad (10.6)$$

The pressure difference Δp is obtained by separate applications of Bernoulli's equation to the two flow regimes of the stream tube.

Referring to region 1–2 in Figure 10.5,

$$p_1 + \frac{1}{2}\rho c_{x1}^2 = p_{2+} + \frac{1}{2}\rho c_{x2}^2$$

and for region 2–3,

$$p_3 + \frac{1}{2}\rho c_{x3}^2 = p_{2-} + \frac{1}{2}\rho c_{x2}^2.$$

By taking the difference of the two equations we obtain

$$\frac{1}{2}\rho(c_{x1}^2 - c_{x3}^2) = p_{2+} - p_{2-}. \quad (10.7)$$

Equating eqns. (10.6) and (10.7) we arrive at the result previously found,

$$c_{x2} = \frac{1}{2}(c_{x1} + c_{x3}). \quad (10.5)$$

The axial flow induction factor is \bar{a} .

By combining eqns. (10.1) and (10.3),

$$P = \rho A_2 c_{x2}^2 (c_{x1} - c_{x3})$$

and from eqn. (10.5) we can obtain

$$c_{x3} = 2c_{x2} - c_{x1};$$

hence,

$$c_{x1} - c_{x3} = c_{x1} - 2c_{x2} + c_{x1} = 2(c_{x1} - c_{x2}),$$

and so

$$P = 2\rho A_2 c_{x2}^2 (c_{x1} - c_{x2}). \quad (10.8)$$

It is convenient to define an *axial flow induction factor*, \bar{a} (invariant with radius), for the actuator disc:

$$\bar{a} = (c_{x1} - c_{x2})/c_{x1}. \quad (10.9)$$

Hence,

$$\begin{aligned} c_{x2} &= c_{x1}(1 - \bar{a}), \\ P &= 2\bar{a}\rho A_2 c_{x1}^3 (1 - \bar{a})^2 \end{aligned} \quad (10.10a)$$

The Power Coefficient

For the unperturbed wind (i.e., velocity is c_{x1}) with the *same* flow area as the disc ($A_2 = \pi R^2$), the kinetic power available in the wind is

$$P_0 = \frac{1}{2} c_{x1}^2 (\rho A_2 c_{x1}) = \frac{1}{2} \rho A_2 c_{x1}^3.$$

A power coefficient C_p is defined as

$$C_p = P/P_0 = 4\bar{a}(1 - \bar{a})^2. \quad (10.11)$$

The maximum value of C_p is found by differentiating C_p with respect to \bar{a} , i.e., finally

$$dC_p/d\bar{a} = 4(1 - \bar{a})(1 - 3\bar{a}) = 0,$$

which gives two roots, $\bar{a} = 1/3$ and 1.0. Using the first value, the maximum value of the power coefficient is

$$C_{p\max} = 16/27 = 0.593. \quad (10.12a)$$

This value of C_p is often referred to as *the Betz limit*, referring to the maximum possible power coefficient of the turbine (with the prescribed flow conditions).

A useful measure of wind turbine performance is the ratio of the power coefficient C_p to the maximum power coefficient $C_{p\max}$. This ratio, which may be called the *relative maximum power coefficient*, is

$$\zeta = 27/16C_p. \quad (10.12b)$$

**FIGURE 10.6**

Variation of Power Coefficient C_p and Axial Force Coefficient C_x as Functions of the Axial Induction Factor \bar{a}

The Axial Force Coefficient

The axial force coefficient is defined as

$$\begin{aligned}
 C_x &= X / \left(\frac{1}{2} \rho c_{x1}^2 A_2 \right) \\
 &= 2\dot{m}(c_{x1} - c_{x2}) / \left(\frac{1}{2} \rho c_{x1}^2 A_2 \right) \\
 &= 4c_{x2}(c_{x1} - c_{x2}) / c_{x1}^2 \\
 &= 4\bar{a}(1 - \bar{a}).
 \end{aligned} \tag{10.13}$$

By differentiating this expression with respect to \bar{a} we can show that C_x has a maximum value of unity at $\bar{a} = 0.5$. Figure 10.6 shows the variation of both C_p and C_x as functions of the axial induction factor, \bar{a} .

Example 10.1

Determine the static pressure changes that take place

- (i) across the actuator disc;
- (ii) up to the disc from far upstream;
- (iii) from the disc to far downstream.

The pressure immediately before the disc is p_{2+} . The pressure immediately after the disc is p_{2-} .

Solution

The force acting on the disc is $X = A_2(p_{2+} - p_{2-}) = A_2\Delta p$. The power developed by the disc is

$$P = Xc_{x2} = A_2\Delta p c_{x2}.$$

Also, we have

$$P = \frac{1}{2} \dot{m} (c_{x1}^2 - c_{x3}^2).$$

Equating for power and simplifying, we get

$$\Delta p / \left(\frac{1}{2} \rho c_{x1}^2 \right) = \left[1 - (c_{x3}/c_{x1})^2 \right] = 1 - (1 - 2\bar{a})^2 = 4\bar{a}(1 - \bar{a}).$$

This is the pressure change across the disc divided by the upstream dynamic pressure.

For the flow field from far upstream of the disc,

$$\begin{aligned} p_{01} &= p_1 + \frac{1}{2} \rho c_{x1}^2 = p_{2+} + \frac{1}{2} \rho c_{x2}^2 \\ (p_{2+} - p_1) &= \frac{1}{2} \rho (c_{x1}^2 - c_{x2}^2) \\ (p_{2+} - p_1) / \left(\frac{1}{2} \rho c_{x1}^2 \right) &= 1 - (c_{x2}/c_{x1})^2 = 1 - (1 - \bar{a})^2 = \bar{a}(2 - \bar{a}). \end{aligned}$$

For the flow field from the disc to far downstream,

$$\begin{aligned} p_{03} &= p_3 + \frac{1}{2} \rho c_{x3}^2 = p_{2-} + \frac{1}{2} \rho c_{x2}^2 \\ (p_{2-} - p_3) / \left(\frac{1}{2} \rho c_{x1}^2 \right) &= (c_{x3}^2 - c_{x2}^2) / c_{x1}^2 \end{aligned}$$

and, noting that $p_3 = p_1$, we finally obtain

$$(p_{2-} - p_1) / \left(\frac{1}{2} \rho c_{x1}^2 \right) = (1 - 2\bar{a})^2 - (1 - \bar{a})^2 = -\bar{a}(2 - 3\bar{a}).$$

Figure 10.7 indicates approximately the way the pressure varies before and after the actuator disc.

FIGURE 10.7

Schematic of the Pressure Variation Before and After the Plane of the Actuator Disc

Example 10.2

Determine the radii of the unmixed slipstream at the disc (R_2) and far downstream of the disc (R_3) compared with the radius far upstream (R_1).

Solution

Continuity requires that

$$\begin{aligned}\pi R_1^2 c_{x1} &= \pi R_2^2 c_{x2} = \pi R_3^2 c_{x3}, \\ (R_2/R_1)^2 &= c_{x1}/c_{x2} = 1/(1-\bar{a}), \quad R_2/R_1 = 1/(1-\bar{a})^{0.5}, \\ (R_3/R_1)^2 &= c_{x1}/c_{x3} = 1/(1-2\bar{a}), \quad R_3/R_1 = 1/(1-2\bar{a})^{0.5}, \\ (R_3/R_2) &= [(1-\bar{a})/(1-2\bar{a})]^{0.5}.\end{aligned}$$

Choosing a value of $\bar{a} = 1/3$, corresponding to the maximum power condition, the radius ratios are $R_2/R_1 = 1.225$, $R_3/R_1 = 1.732$ and $R_3/R_2 = 1.414$.

Example 10.3

Using the preceding expressions for an actuator disc, determine the power output of a HAWT of 30 m tip diameter in a steady wind blowing at

- (i) 7.5 m/s;
- (ii) 10 m/s.

Assume that the air density is 1.2 kg/m^3 and that $\bar{a} = 1/3$.

Solution

Using eqn. (10.10a) and substituting $\bar{a} = 1/3$, $\rho = 1.2 \text{ kg/m}^3$ and $A_2 = \pi 15^2$,

$$P = 2\bar{a}\rho A_2 c_{x1}^3 (1-\bar{a})^2 = \frac{2}{3} \times 1.2 \times \pi 15^2 \times \left(1 - \frac{1}{3}\right)^2 c_{x1}^3 = 251.3 c_{x1}^3.$$

- (i) With $c_{x1} = 7.5 \text{ m/s}$, $P = 106 \text{ kW}$.
- (ii) With $c_{x1} = 10 \text{ m/s}$, $P = 251.3 \text{ kW}$.

These two results give some indication of the power available in the wind.

Correcting for High Values of \bar{a}

It is of some interest to examine the theoretical implications of what happens at high values of \bar{a} and compare this with what is found experimentally. From the actuator disc analysis we found that the velocity in the wake far downstream was determined by $c_{x3} = c_{x1}(1-2\bar{a})$, and this becomes zero when $\bar{a} = 0.5$. In other words the actuator disc model has already failed as there can be no flow

when $\bar{a} = 0.5$. It is as if a large flat plate had been put into the flow, completely replacing the rotor. Some opinion has it that the theoretical model does not hold true for values of \bar{a} even as low as 0.4. So, it becomes necessary to resort to empirical methods to include physical reality.

Figure 10.8 shows experimental values of C_X for heavily loaded turbines plotted against \bar{a} , taken from various sources, together with the theoretical curve of C_X versus \bar{a} given by eqn. (10.13). The part of this curve in the range $0.5 < \bar{a} < 1.0$, shown by a broken line, is invalid as already explained. The experiments revealed that the vortex structure of the flow downstream disintegrates and that wake mixing with the surrounding air takes place. Various authors including Glauert (1935), Wilson and Walker (1976), and Anderson (1980), have presented curves to fit the data points in the regime $\bar{a} > 0.5$. Anderson obtained a simple “best fit” of the data with a straight line drawn from a point denoted by C_{XA} located at $\bar{a} = 1.0$ to a tangent point T , the transition point, on the theoretical curve located at $\bar{a} = \bar{a}_T$. It is easy to show, by differentiation of the curve $C_X = 4\bar{a}(1 - \bar{a})$ then fitting a straight line, with the equation,

$$C_X = C_{XA} - 4(C_{XA}^{0.5} - 1)(1 - \bar{a}), \quad (10.14)$$

where

$$\bar{a}_T = 1 - \frac{1}{2}C_{XA}^{0.5}.$$

Anderson recommended a value of 1.816 for C_{XA} . Using this value, eqn. (10.14) reduces to

$$C_X = 0.4256 + 1.3904\bar{a}, \quad (10.15a)$$

where $\bar{a}_T = 0.3262$.

Sharpe (1990) noted that, for most practical, existent HAWTs, the value of \bar{a} rarely exceeds 0.6.

FIGURE 10.8

Comparison of Theoretical Curve and Measured Values of C_X

10.5 ESTIMATING THE POWER OUTPUT

Preliminary estimates of rotor diameter can easily be made using simple actuator disc theory. A number of factors need to be taken into account, i.e., the wind regime in which the turbine is to operate and the tip-speed ratio. Various losses must be allowed for, the main ones being the mechanical transmission including gearbox losses and the electrical generation losses. From the actuator disc theory the turbine aerodynamic power output is

$$P = \frac{1}{2} \rho A_2 C_p c_{x1}^3. \quad (10.15b)$$

Under theoretical ideal conditions the maximum value of $C_p = 0.593$. According to Eggleston and Stoddard (1987), rotor C_p values as high as 0.45 have been reported. Such high, real values of C_p relate to very precise, smooth aerofoil blades and tip-speed ratios above 10. For most machines of good design a value of C_p from 0.3 to 0.35 would be possible. With a drive train efficiency, η_d , and an electrical generation efficiency, η_g , the output electrical power would be

$$P_{el} = \frac{1}{2} \rho A_2 C_p \eta_g \eta_d c_{x1}^3.$$

Example 10.4

Determine the size of rotor required to generate 20 kW of electrical power in a steady wind of 7.5 m/s. It can be assumed that the air density, $\rho = 1.2 \text{ kg/m}^3$, $C_p = 0.35$, $\eta_g = 0.75$, and $\eta_d = 0.85$.

Solution

From this expression the disc area is

$$A_2 = 2P_{el} / (\rho C_p \eta_g \eta_d c_{x1}^3) = 2 \times 20 \times 10^3 / (1.2 \times 0.35 \times 0.75 \times 0.85 \times 7.5^3) = 354.1 \text{ m}^2.$$

Hence, the diameter is 21.2 m.

10.6 POWER OUTPUT RANGE

The kinetic power available in the wind is

$$P_0 = \frac{1}{2} \rho A_2 c_{x1}^3, \quad (10.10b)$$

where A_2 is the disc area and c_{x1} is the velocity upstream of the disc. The ideal power generated by the turbine can therefore be expected to vary as the cube of the wind speed. Figure 10.9 shows the idealised power curve for a wind turbine, where the preceding cubic “law” applies between the so-called *cut-in* wind speed and the *rated wind speed* at which the maximum power is first reached. The cut-in speed is the lowest wind speed at which net (or positive) power is produced by the turbine. The rated wind speed generally corresponds to the point at which the efficiency of energy conversion is close to its maximum.

**FIGURE 10.9**

Idealised Power Curve for a Wind Turbine

At wind speeds greater than the rated value, for most wind turbines, the power output is maintained constant by aerodynamic controls [discussed in Section 10.13, Control Methods (Starting, Modulating, and Stopping)]. The *cut-out wind speed* is the maximum permitted wind speed which, if reached, causes the control system to activate braking, bringing the rotor to rest.

10.7 BLADE ELEMENT THEORY

Introduction

It has long been recognised that the work of Glauert (1935) in developing the fundamental theory of aerofoils and airscrews is among the great classics of aerodynamic theory. Glauert also generalised the theory to make it applicable to wind turbines and, with various modifications, it is still used in turbine design. It is often referred to as the *momentum vortex blade element theory* or more simply as the *blade element method*. However, the original work neglected an important aspect: the flow periodicity resulting from the turbine having a finite number of blades. Glauert assumed that elementary radial blade sections could be analysed independently, which is valid only for a rotor with an infinite number of blades. However, several approximate solutions are available (those of Prandtl and Tietjens, 1957, and Goldstein, 1929), which enable compensating corrections to be made for a finite number of blades. The simplest and most often used of these, called the *Prandtl correction factor*, will be considered later in this chapter. Another correction that is considered is empirical and applies only to heavily loaded turbines when the magnitude of the axial flow induction factor \bar{a} exceeds the acceptable limit of the momentum theory. According to Sharpe (1990) the flow field of heavily loaded turbines is not well understood and the results of the empirical analysis mentioned are only approximate but better than those predicted by the momentum theory.

The Vortex System of an Aerofoil

To derive a better understanding of the aerodynamics of the HAWT than was obtained earlier from simple actuator disc theory, it is now necessary to consider the forces acting on the blades. We may

**FIGURE 10.10**

Schematic Drawing of the Vortex System Convecting Downstream of a Two-Bladed Wind Turbine Rotor

regard each radial element of a blade as an aerofoil. The turbine is assumed to have a constant angular speed Ω and is situated in a uniform wind of velocity c_{x1} parallel to the axis of rotation. The lift force acting on each element must have an associated *circulation* (see, in section 3.4, Circulation and Lift) around the blade. In effect there is a line vortex (or a set of line vortices) along the aerofoil span. The line vortices that move with the aerofoil are called *bound vortices* of the aerofoil. As the circulation along the blade length can vary, *trailing vortices* will spring from the blade and will be convected downstream with the flow in approximately helical paths, as indicated for a two-bladed wind turbine in Figure 10.10. It will be observed that the helices, as drawn, gradually expand in radius as they move downstream (at the wake velocity) and the pitch between each sheet becomes smaller because of the deceleration of the flow (see Figure 10.5).

Torque, τ and the Tangential Flow Induction Factor, a'

From Newton's laws of motion it is evident that the torque exerted on the turbine shaft must impart an equal and opposite torque on the airflow equal to the rate of change of the angular momentum of the flow. There is no rotation of the flow upstream of the blades or outside of the boundary stream tube.

According to Glauert, this rotational motion is to be ascribed partly to the system of trailing vortices and partly to the circulation around the blades. Due to the trailing vortices, the flow *in the plane of the turbine blades* will have an angular velocity $a'\Omega$ in the direction opposite to the blade rotation, and the circulation around the blades will cause equal and opposite angular velocities to the flows immediately upstream and downstream of the turbine blades. The sum of these angular velocity components, of

course, is zero upstream of the blades, because no rotation is possible until the flow reaches the vortex system generated by the blades. It follows from this that the angular velocity downstream of the blades is $2a'\Omega$ and the interference flow, which acts on the blade elements, will have the angular velocity $a'\Omega$. These deliberations will be of some importance when the velocity diagram for the turbine flow is considered (see Figure 10.11).

Glauert regarded the exact evaluation of the interference flow to be of great complexity because of the periodicity of the flow caused by the blades. He asserted that for most purposes it is sufficiently accurate to use circumferentially averaged values, equivalent to assuming that the thrust and the torque carried by the finite number of blades are replaced by uniform distributions of thrust and torque *spread over the whole circumference* at the same radius.

Consider such an elementary annulus of a HAWT of radius r from the axis of rotation and of radial thickness dr . Let $d\tau$ be the element of torque equal to the rate of decrease in angular momentum of the wind passing through the annulus. Thus,

FIGURE 10.11

(a) Blade Element at Radius r Moving from Right to Left Showing the Various Velocity Components. The Relative Velocity Impinging onto the Blade is w_2 at Relative Flow Angle ϕ and Incidence Angle α . (b) The Various Force Components Acting on the Blade Section.

$$d\tau = (dm) \times 2a'\Omega r^2 = (2\pi r dr \rho c_{x2}) \times 2a'\Omega r^2 \quad (10.16a)$$

or

$$d\tau = 4\pi\rho\Omega c_{x1}(1-a)a'r^3 dr. \quad (10.16b)$$

In the actuator disc analysis the value of a (denoted by \bar{a}) is a constant over the whole of the disc. With blade element theory the value of a is a function of the radius. This is a fact that must not be overlooked. A constant value of a *could* be obtained for a wind turbine design with blade element theory, but only by varying the chord and the pitch in some special way along the radius. This is not a useful design requirement.

Assuming the axial and tangential induction factors a and a' are functions of r we obtain an expression for the power developed by the blades by multiplying the above expression by Ω and integrating from the hub r_h to the tip radius R :

$$P = 4\pi\rho\Omega^2 c_{x1} \int_{r_h}^R (1-a)a'r^3 dr. \quad (10.17)$$

Forces Acting on a Blade Element

Consider now a turbine with Z blades of tip radius R each of chord l at radius r and rotating at angular speed Ω . The pitch angle of the blade at radius r is β measured from the zero lift line to the plane of rotation. The axial velocity of the wind at the blades is the same as the value determined from actuator disc theory, i.e., $c_{x2} = c_{x1}(1-a)$, and is perpendicular to the plane of rotation.

Figure 10.11 shows the blade element moving from right to left together with the velocity vectors relative to the blade chord line at radius r . The resultant of the relative velocity immediately upstream of the blades is,

$$w = [c_{x1}^2(1-a)^2 + (\Omega r)^2(1+a')^2]^{0.5}, \quad (10.18)$$

and this is shown as impinging onto the blade element at angle ϕ to the plane of rotation. It will be noticed that the tangential component of velocity contributing to w is the blade speed augmented by the interference flow velocity, $a'\Omega r$. The following relations will be found useful in later algebraic manipulations:

$$\sin \phi = c_{x2}/w = c_{x1}(1-a)/w, \quad (10.19)$$

$$\cos \phi = \Omega r(1+a')/w, \quad (10.20)$$

$$\tan \phi = \frac{c_{x1}}{\Omega r} \left(\frac{1-a}{1+a'} \right). \quad (10.21)$$

Figure 10.11 shows the lift force L and the drag force D drawn (by convention) perpendicular and parallel to the relative velocity at entry, respectively. In the normal range of operation, D although rather small (1–2%) compared with L , is not to be entirely ignored. The resultant force, R , is seen as having a component in the direction of blade motion. This is the force contributing to the positive power output of the turbine.

From Figure 10.11 the force per unit blade length in the direction of motion is

$$Y = L \sin \phi - D \cos \phi, \quad (10.22)$$

and the force per unit blade length in the axial direction is

$$X = L \cos \phi + D \sin \phi. \quad (10.23)$$

Lift and Drag Coefficients

We can define the lift and drag coefficients as

$$C_L(\alpha) = L / \left(\frac{1}{2} \rho w^2 l \right), \quad (10.24)$$

$$C_D(\alpha) = D / \left(\frac{1}{2} \rho w^2 l \right), \quad (10.25)$$

where, by the convention employed for an isolated aerofoil, w is the incoming relative velocity and l is the blade chord. The coefficients C_L and C_D are functions of the angle of incidence, $\alpha = \phi - \beta$, as defined in Figure 10.11, as well as the blade profile and blade Reynolds number. In this chapter the angle of incidence is understood to be measured from the *zero lift line* (see Chapter 5, Section 5.15, Lift Coefficient of a Fan Aerofoil) for which the C_L versus α curve goes through zero. It is important to note that Glauert (1935), when considering aerofoils of small camber and thickness, obtained a theoretical expression for the lift coefficient,

$$C_L = 2\pi \sin \alpha. \quad (10.26)$$

The theoretical slope of the curve of lift coefficient against incidence is 2π per radian (for small values of α) or 0.11 per degree but, from experimental results, a good average generally accepted is 0.1 per degree *within the pre-stall regime*. This very useful result will be used extensively in calculating results later. However, measured values of the lift-curve slope reported by Abbott and von Doenhoff (1959) for a number of NACA four- and five-digit series and NACA 6-series wing sections, measured at a Reynolds number of 6×10^6 , gave 0.11 per degree. But, these blade profiles were intended for aircraft wings, so some departure from the rule might be expected when the application is the wind turbine.

Again, within the pre-stall regime, values of C_D are small and the ratio of C_D/C_L is usually about 0.01. Figure 10.12 shows typical variations of lift coefficient C_L plotted against incidence α and drag coefficient C_D plotted against C_L for a wind turbine blade tested beyond the stall state. The blades of a wind turbine may occasionally have to operate in *post-stall conditions* when C_D becomes large; then the drag term needs to be included in performance calculations. Details of *stall modelling* and formulae for C_D and C_L under post-stall conditions are given by Eggleston and Stoddard (1987).

The correct choice of aerofoil sections is very important for achieving good performance. The design details and the resulting performance are clearly competitive and not much information is actually available in the public domain. The U.S. Department of Energy (DOE) developed a series of aerofoils specifically for wind turbine blades. These aerofoils were designed to provide the necessarily different performance characteristics from the blade root to the tip while accommodating the structural requirements. Substantially increased energy output (from 10 to 35%) from wind turbines with these

**FIGURE 10.12**

Typical Performance Characteristics for a Wind Turbine Blade, C_L versus a and C_D versus C_L

new blades have been reported. The data are catalogued and is available to the U.S. wind industry.² Many other countries have national associations, research organisations, and conferences relating to wind energy and contact details are listed by Ackermann and Söder (2002).

Connecting Actuator Disc Theory and Blade Element Theory

The elementary axial force and elementary force exerted on *one* blade of length dr at radius r are

$$dX = (L \cos \phi + D \sin \phi)dr,$$

$$d\tau = r(L \sin \phi - D \cos \phi)dr.$$

For a turbine having Z blades and using the definitions for C_L and C_D given by eqns. (10.24) and (10.25), we can write expressions for the elementary torque, power and thrust as

$$d\tau = \frac{1}{2} \rho w^2 r (C_L \sin \phi - C_D \cos \phi) Z dr, \quad (10.27)$$

$$dP = \Omega d\tau = \frac{1}{2} \rho w^2 \Omega r (C_L \sin \phi - C_D \cos \phi) Z dr, \quad (10.28)$$

$$dX = \frac{1}{2} \rho w^2 (C_L \cos \phi + C_D \sin \phi) Z dr. \quad (10.29)$$

It is now possible to make a connection between actuator disc theory and blade element theory. (Values of a and a' are allowed to vary with radius in this analysis.) From eqn. (10.2), for an element of the flow, we obtain

$$dX = d\dot{m}(c_{x1} - c_{x3}) = d\dot{m}c_{x2}2a/(1-a). \quad (10.30)$$

²See Section 10.11, HAWT Blade Section Criteria, for more details.

Equating eqns. (10.29) and (10.30) and with some rearranging, we get

$$a/(1-a) = Zl(C_L \cos \phi + C_D \sin \phi)/(8\pi r \sin^2 \phi). \quad (10.31)$$

Again, considering the tangential momentum, from eqn. (10.16a) the elementary torque is

$$d\tau = (2\pi r dr) \rho c_{x2}(rc_\theta).$$

Equating this with eqn. (10.27) and simplifying, we get

$$c_{x2}c_\theta/w^2 = Zl(C_L \sin \phi - C_D \cos \phi)/(4\pi r). \quad (10.32)$$

Using eqn. (10.20) we find

$$c_\theta/w = Ua' \cos \phi/[U(1+a')] = 2a' \cos \phi/(1+a')$$

and, with eqn. (10.19), eqn. (10.32) becomes

$$a'/(1+a') = Zl(C_L \sin \phi - C_D \cos \phi)/(8\pi r \sin \phi \cos \phi). \quad (10.33)$$

Introducing a useful new dimensionless parameter, the *blade loading coefficient*,

$$\lambda = ZlC_L/(8\pi r), \quad (10.34)$$

into eqns. (10.31) and (10.33), we get

$$a/(1-a) = \lambda(\cos \phi + \varepsilon \sin \phi)/\sin^2 \phi, \quad (10.35a)$$

$$a'/(1+a') = \lambda(\sin \phi - \varepsilon \cos \phi)/(\sin \phi \cos \phi), \quad (10.36a)$$

$$\varepsilon = \frac{C_D}{C_L} \quad (10.37)$$

Tip-Speed Ratio

A most important non-dimensional parameter for the rotors of HAWTs is the tip-speed ratio, defined as

$$J = \frac{\Omega R}{c_{x1}}. \quad (10.38)$$

This parameter controls the operating conditions of a turbine and strongly influences the values of the flow induction factors, a and a' .

Using eqn. (10.38) in eqn. (10.21) we write the tangent of the relative flow angle ϕ as

$$\tan \phi = \frac{R}{rJ} \left(\frac{1-a}{1+a'} \right). \quad (10.39)$$

Turbine Solidity

A primary non-dimensional parameter that characterises the geometry of a wind turbine is the blade solidity, σ . The solidity is defined as the ratio of the blade area to the disc area:

$$\sigma = ZA_B/(\pi R^2),$$

where

$$A_B = \int l(r) dr = \frac{1}{2} R l_{av}.$$

This is usually written as

$$\sigma = Z l_{av} / (2\pi R), \quad (10.40)$$

where l_{av} is the mean blade chord.

Solving the Equations

The foregoing analysis provides a set of relations which can be solved by a process of iteration, enabling a and a' to be determined for any specified pitch angle β , provided that convergence is possible. To obtain faster solutions, we will use the approximation that $\varepsilon \cong 0$ in the normal efficient range of operation (i.e., the pre-stall range). Equations (10.35a) and (10.36a) can now be written as

$$a/(1-a) = \lambda \cot \phi / \sin \phi, \quad (10.35b)$$

$$a'/(1+a') = \lambda / \cos \phi. \quad (10.36b)$$

These equations are about as simple as it is possible to make them and they will be used to model some numerical solutions.

Example 10.5

Consider a three-bladed HAWT with a rotor 30 m diameter, operating with a tip-speed ratio $J = 5.0$. The blade chord is assumed to be constant at 1.0 m. Assuming that the drag coefficient is negligible compared with the lift coefficient, determine using an iterative method of calculation the appropriate values of the axial and tangential induction factors at $r/R = 0.95$ where the pitch angle β is 2° .

Solution

It is best to start the calculation process by putting $a = a' = 0$. The values, of course, will change progressively as the iteration proceeds. Thus, using eqn. (10.39),

$$\tan \phi = (R/rJ)(1-a)/(1+a') = 1/(0.95 \times 5) = 0.2105.$$

Therefore,

$$\phi = 11.89^\circ \text{ and } \alpha = \phi - \beta = 9.89^\circ.$$

Using the approximation (see earlier) that $C_L = 0.1 \times \alpha = 0.989$, then

$$\lambda = (Z C_L) / (8\pi r) = 0.00884 \times C_L = 0.008743,$$

$$1/a = 1 + (1/\lambda) \sin \phi \tan \phi = 1 + 114.38 \times \sin 11.89^\circ \times \tan 11.89^\circ = 5.962.$$

Table 10.1 BEM Method for Evaluating a and a'

Step	Action Required
1	Initialise a and a' with zero values
2	Evaluate the flow angle using eqn. (10.39)
3	Evaluate the local angle of incidence, $\alpha = \phi - \beta$
4	Determine C_L and C_D from tables (if available) or from formula
5	Calculate a and a'
6	Check on convergence of a and a' , if not sufficient go to step 2, else go to step 7
7	Calculate local forces on the element

Thus,

$$a = 0.1677,$$

$$1/a' = (1/\lambda) \cos \phi - 1 = 110.9,$$

$$a' = 0.00902.$$

Using these new values of a and a' in eqn. (10.39), the calculation is repeated iteratively until convergence is achieved, usually taking another four or five cycles (but in calculations where if $a > 0.3$, many more iterations will be needed). Finally, and with sufficient accuracy,

$$a = 0.1925 \text{ and } a' = 0.00685.$$

Also, $\phi = 9.582^\circ$ and $C_L = 0.1 \times (\phi - \beta) = 0.758$.

It may be advisable at this point for the student to devise a small computer program (if facilities are available) or use a programmable hand calculator for calculating further values of a and a' . (Even a simple scientific calculator will yield results, although more tediously.) An outline of the algorithm, called the *BEM method*, is given in Table 10.1, which is intended to become an important and useful time-saving tool. Further extension of this method will be possible as the theory is developed.

10.8 THE BLADE ELEMENT MOMENTUM METHOD

All the theory and important definitions to determine the force components on a blade element have been introduced and a first trial approach has been given to finding a solution in Example 10.5. The various steps of the classical BEM model from Glauert are formalised in Table 10.1 as an algorithm for evaluating a and a' for each elementary control volume.

Spanwise Variation of Parameters

Along the blade span there is a significant variation in the blade pitch angle β , which is strongly linked to the value of J and to a lesser extent to the values of the lift coefficient C_L and the blade chord l .

The ways both C_L and l vary with radius are at the discretion of the turbine designer. In the previous example the value of the pitch angle was specified and the lift coefficient was derived (together with other factors) from it. We can likewise specify the lift coefficient, keeping the incidence below the angle of stall and from it determine the angle of pitch. This procedure will be used in the next example to obtain the spanwise variation of β for the turbine blade. It is certainly true that for optimum performance the blade *must* be twisted along its length with the result that, near the root, there is a large pitch angle. The blade pitch angle will decrease with increasing radius so that, near the tip, it is close to zero and may even become slightly negative. The blade chord in the following examples has been kept constant to limit the number of choices. Of course, most turbines in operation have tapered blades whose design features depend upon blade strength as well as economic and aesthetic considerations.

Example 10.6

A three-bladed HAWT with a 30 m tip diameter is to be designed to operate with a constant lift coefficient $C_L = 0.8$ along the span, with a tip-speed ratio $J = 5.0$. Assuming a constant chord of 1.0 m, determine, using an iterative method of calculation, the variation along the span ($0.2 \leq r/R \leq 1.0$) of the flow induction factors a and a' and the pitch angle β .

Solution

We begin the calculation at the tip, $r = 15$ m and, as before, take initial values for a and a' of zero. Now,

$$\lambda = (Z/C_L)/(8\pi r) = (3 \times 0.8)/(8 \times \pi \times 15) = 0.006366, \text{ and } 1/\lambda = 157.1;$$

$$\tan \phi = (R/rJ)(1 - a)/(1 + a') = 0.2, \quad \phi = 11.31^\circ;$$

$$1/a = 1 + 157.1 \times \sin 11.31^\circ \times \tan 11.31^\circ = 7.162, \quad a = 0.1396;$$

$$1/a' = 157.1 \times \cos 11.31^\circ - 1 = 153.05, \quad a' = 0.00653.$$

After a further five iterations (to obtain sufficient convergence) the result is

$$a = 0.2054, \quad a' = 0.00649, \quad \text{and } \beta = 0.97^\circ.$$

The results of the computations along the complete span ($0.2 \leq r/R \leq 1.0$) for a and a' are shown in Table 10.2. It is very evident that the parameter a varies markedly with radius, unlike the actuator disc application where \bar{a} was constant. The spanwise variation of the pitch angle β for $C_L = 0.8$ (as well as for $C_L = 1.0$ and 1.2 for comparison) is shown in Figure 10.13. The large variation of β along the span is not surprising and is linked to the choice of the value of J , the tip-speed ratio. The choice of inner radius ratio $r/R = 0.2$ was arbitrary. However, the contribution to the power developed from choosing an even smaller radius would have been negligible.

Table 10.2 Summary of Results Following Iterations

r/R	0.2	0.3	0.4	0.6	0.8	0.9	0.95	1.0
ϕ	42.29	31.35	24.36	16.29	11.97	10.32	9.59	8.973
β	34.29	23.35	16.36	8.29	3.97	2.32	1.59	0.97
a	0.0494	0.06295	0.07853	0.1138	0.1532	0.1742	0.1915	0.2054
a'	0.04497	0.0255	0.01778	0.01118	0.00820	0.00724	0.00684	0.00649

Note: $C_L = 0.8$ along the span.

**FIGURE 10.13**

Variation of Blade Pitch Angle β with Radius Ratio r/R for $C_L = 0.8, 1.0$ and 1.2 (See Example 10.6 for Conditions)

Evaluating the Torque and Axial Force

The incremental axial force can be derived from eqns. (10.29) and (10.19) in the form

$$\Delta X = \frac{1}{2} \rho Z l R c_{x1}^2 [(1 - a) / \sin \phi]^2 C_L \cos \phi \Delta(r/R) \quad (10.41)$$

and the incremental torque can be derived from eqns. (10.27) and (10.20) as

$$\Delta \tau = \frac{1}{2} \rho Z l \Omega^2 R^4 [(1 + a') / \cos \phi]^2 (r/R)^3 C_L \sin \phi \Delta(r/R). \quad (10.42)$$

In determining numerical solutions, these two equations have proved to be more reliable in use than some alternative forms that have been published. The two preceding equations will now be integrated numerically.

Example 10.7

Determine the total axial force, the torque, the power, and the power coefficient of the wind turbine described in Example 10.5. Assume that $c_{x1} = 7.5$ m/s and that the air density $\rho = 1.2$ kg/m³.

Solution

Evaluating the elements of axial force ΔX having previously determined the mid-ordinate values of a , a' , and ϕ to gain greater accuracy (the relevant data is shown in Table 10.3):

$$\Delta X = \frac{1}{2} \rho Z l R c_{x1}^2 [(1 - a) / \sin \phi]^2 C_L \cos \phi \Delta(r/R),$$

where, in Table 10.3, Var. 1 = $[(1 - a)/\sin \phi]^2 C_L \cos \phi \Delta(r/R)$:

$$\sum \text{Var.1} = 6.9682.$$

Then with $\frac{1}{2}\rho ZIRc_{x1}^2 = \frac{1}{2} \times 1.2 \times 3 \times 15 \times 7.5^2 = 1518.8$, we obtain

$$X = 1518.8 \sum \text{Var.1} = 10,583 \text{ N.}$$

In Table 10.4, Var. 2 = $[(1 + a')/\cos \phi]^2 (r/R)^3 C_L \sin \phi \Delta(r/R)$,

$$\sum \text{Var.2} = 47.509 \times 10^{-3}$$

and with $\frac{1}{2}\rho ZI\Omega^2 R^4 = 0.5695 \times 10^6$,

$$\tau = 27.058 \times 10^3 \text{ Nm.}$$

Hence, the power developed is $P = \tau\Omega = 67.644 \text{ kW}$. The power coefficient is, see eqn. (10.11), is

$$C_p = \frac{P}{P_0} = \frac{P}{0.5\rho A_2 c_{x1}^3} = \frac{P}{1.789 \times 10^5} = 0.378$$

and the relative power coefficient is, see eqn. (10.12b),

$$\zeta = \frac{27}{16} C_p = 0.638.$$

Example 10.8

The relationship between actuator disc theory and blade element theory can be more firmly established by evaluating the power again, this time using the actuator disc equations.

Solution

To do this we need to determine the equivalent constant value for \bar{a} . From eqn. (10.13),

$$C_x = 4\bar{a}(1 - \bar{a}) = X / \left(\frac{1}{2} \rho c_{x1}^2 A_2 \right),$$

with $X = 10,583$ N and $\frac{1}{2} \rho c_{x1}^2 A_2 = \frac{1}{2} \times 1.2 \times 7.5^2 \times \pi \times 15^2 \times 23,856$, we obtain

$$C_x = 10,583 / 23,856 = 0.4436,$$

$$\bar{a}(1 - \bar{a}) = 0.4436 / 4 = 0.1109.$$

Solving the quadratic equation, we get $\bar{a} = 0.12704$.

From eqn. (10.10a), $P = 2\rho A_2 c_{x1}^3 \bar{a}(1 - \bar{a})^2$, and substituting values,

$$P = 69.286 \text{ kW},$$

and this agrees fairly well with the value obtained in Example 10.7.

Note: The lift coefficient used in this example, admittedly modest, was selected purely to illustrate the method of calculation. For an initial design, the equations just developed would suffice but some further refinements can be added. An important refinement concerns the Prandtl correction for the number of blades.

Correcting for a Finite Number of Blades

So far, the analysis has ignored the effect of having a finite number of blades. The fact is that at a fixed point the flow fluctuates as a blade passes by. The induced velocities at the point are not constant with time. The overall effect is to reduce the net momentum exchange and the net power of the turbine. Some modification of the analysis is needed and this is done by applying a blade tip correction factor. Several solutions are available: (i) an exact one due to Goldstein (1929), represented by an infinite series of modified Bessel functions, and (ii) a closed form approximation due to Prandtl and Tietjens (1957). Both methods give similar results and Prandtl's method is the one usually preferred.

Prandtl's Correction Factor

The mathematical details of Prandtl's analysis are beyond the scope of this book, but the result is usually expressed as

$$F = (2/\pi) \cos^{-1} [\exp(-\pi d/s)], \quad (10.43)$$

where, as shown in Figure 10.14, s is the pitchwise distance between the successive helical vortex sheets and $d = R - r$. From the geometry of the helices,

$$s = (2\pi R/Z) \sin \phi,$$

**FIGURE 10.14**

Prandtl Tip Loss Model Showing the Distances Used in the Analysis

where $\sin \phi = c_{x2}/w$. Thus,

$$s = 2\pi(1-a)Rc_{x1}/(wZ),$$

$$\pi d/s = \frac{1}{2}Z(1-r/R)w/c_{x2} = \frac{1}{2}Z(1-r/R)/\sin \phi. \quad (10.44a)$$

This can be evaluated with sufficient accuracy and perhaps more conveniently with the approximation,

$$\pi d/s = \frac{1}{2}Z(1-r/R)(1+J^2)^{0.5}. \quad (10.44b)$$

The circulation at the blade tips reduces to zero because of the vorticity shed from it, in the same way as at the tip of an aircraft wing. These expressions ensure that F becomes zero when $r = R$ but rapidly increases towards unity with decreasing radius.

The variation of $F = F(r/R)$ is shown in Figure 10.15 for $J = 5$ and $Z = 2, 3, 4$, and 6 . It will be clear from the graph and the preceding equations that the greater the pitch s and the smaller the number of blades Z , the bigger will be the variation of F (from unity) at any radius ratio. In other words the amplitude of the velocity fluctuations will be increased.

Prandtl's tip correction factor is applied directly to each blade element, modifying the elementary axial force, obtained from eqn. (10.13),

$$dX = 4\pi\rho a(1-a)rc_{x1}^2 dr$$

to become

$$dX = 4\pi\rho a(1-a)rc_{x1}^2 F dr \quad (10.45)$$

and the elementary torque, eqn. (10.16b),

$$d\tau = 4\pi\rho\Omega c_{x1}(1-a)a'r^3 dr$$

is modified to become

$$d\tau = 4\pi\rho\Omega c_{x1}(1-a)a'Fr^3 dr. \quad (10.46)$$

Following the reduction processes that led to eqns. (10.35) and (10.36), the last two numbered equations give the following results:

FIGURE 10.15

Variation of Prandtl Correction Factor F with Radius Ratio for Blade Number $Z=2, 3, 4$, and 6

$$a/(1-a) = \lambda(\cos \phi + \varepsilon \sin \phi)/(F \sin^2 \phi), \quad (10.47a)$$

$$a'/(1+a') = \lambda(\sin \phi - \varepsilon \cos \phi)/(F \sin \phi \cos \phi). \quad (10.48a)$$

The application of the Prandtl tip correction factor to the elementary axial force and elementary torque equations has some important implications concerning the overall flow and the interference factors. The basic meaning of eqn. (10.45) is

$$dX = d\dot{m}(2aFc_{x1}),$$

i.e., the average axial induction factor in the far wake is $2aF$ when the correction factor is applied as opposed to $2a$ when it is not. Note also that, in the plane of the disc (or the blades), the average induction factor is aF , and that the axial velocity becomes

$$c_{x2} = c_{x1}(1 - aF).$$

From this we see that at the tips of the blades $c_{x2} = c_{x1}$, because F is zero at that radius.

Note: It was explained earlier that the limit of application of the theory occurs when $a \rightarrow 0.5$, i.e., $c_{x2} = c_{x1}(1 - 2a)$, and, as the earlier calculations have shown, a is usually greatest towards the blade tip. However, with the application of the tip correction factor F , the limit state becomes $aF = 0.5$. As F progressively reduces to zero as the blade tip is approached, the operational result gives, in effect, some additional leeway in the convergence of the iterative procedure discussed earlier.

Performance Calculations with Tip Correction Included

In accordance with the previous approximation (to reduce the amount of work needed), ε is ascribed the value zero, simplifying the preceding equations for determining a and a' to

$$a/(1-a) = \lambda \cos \phi / (F \sin^2 \phi), \quad (10.47b)$$

$$a'/(1+a') = \lambda / (F \cos \phi). \quad (10.48b)$$

When using the BEM method an extra step is required in Table 10.1, between steps 1 and 2, to calculate F , and it is necessary to calculate a new value of C_L for each iteration that, consequently, changes the value of the blade loading coefficient λ as the calculation progresses.

Example 10.9

This example repeats the calculations of Example 10.7 using the same blade specification [i.e., the pitch angle $\beta = \beta(r)$] but now it includes the Prandtl correction factor. The results of the iterations to determine a , a' , ϕ , and C_L and used as data for the summations are shown in Table 10.5. The details of the calculation for one mid-ordinate radius ($r/R = 0.95$) are shown first to clarify the process.

Solution

At $r/R = 0.95$, $F = 0.522$, using eqns. (10.44b) and (10.43). Thus, with $Z = 3$, $l = 1.0$,

$$F/\lambda = 62.32/C_L.$$

In the BEM method we start with $a = a' = 0$ so, initially, $\tan \phi = (R/r)/J = (1/0.95)/5 = 0.2105$. Thus, $\phi = 11.89^\circ$ and $C_L = (\phi - \beta)/10 = (11.89 - 1.59)/10 = 1.03$. Hence, $F/\lambda = 60.5$. With eqns. (10.47a) and (10.48a) we compute $a = 0.2759$ and $a' = 0.0172$.

The next cycle of iteration gives $\phi = 8.522$, $C_L = 0.693$, $F/\lambda = 89.9$, $a = 0.3338$, and $a' = 0.0114$. Continuing the series of iterations we finally obtain

$$a = 0.351, \quad a' = 0.010, \quad \phi = 7.705, \quad \text{and} \quad C_L = 0.6115.$$

For the elements of force,

$$\Delta X = \frac{1}{2} \rho Z l R c_{x1}^2 [(1-a)/\sin \phi]^2 \cos \phi C_L \Delta(r/R).$$

Table 10.5 Summary of Results for All Mid-ordinates

Mid r/R	0.250	0.350	0.450	0.550	0.650	0.750	0.850	0.950
F	1.0	1.0	0.9905	0.9796	0.9562	0.9056	0.7943	0.522
C_L	0.8	0.8	0.796	0.790	0.784	0.7667	0.7468	0.6115

Var. 2×10^{-3}	1.2203	2.097	3.215	4.541	6.033	7.526	8.773	7.302

Table 10.7 Summary of Results

	Axial force, kN	Power, kW	C_P	ζ
Without tip correction	10.583	67.64	0.378	0.638
With tip correction	9.848	57.96	0.324	0.547

Where, in Table 10.5, Var. 1 = $[(1 - a)/\sin \phi]^2 \cos \phi C_L \Delta(r/R)$,

$$\sum \text{Var.1} = 6.3416.$$

As in Example 10.6, $\frac{1}{2} Z I R c_{x1}^2 = 1518.8$, then

$$X = 1518.8 \times 6.3416 = 9,631 \text{ N}.$$

Evaluating the elements of the torque using eqn. (10.42), where, in Table 10.6, Var. 2 = $[(1 + a')/\cos \phi]^2 (r/R)^3 C_L \sin \phi \Delta(r/R)$,

$$\sum \text{Var.2} = 40.707 \times 10^{-3} \text{ and } \frac{1}{2} \rho Z I \Omega^2 R^4 = 0.5695 \times 10^6,$$

then

$$\tau = 23.183 \times 10^3 \text{ Nm}.$$

Hence, $P = \tau \Omega = 57.960 \text{ kW}$, $C_P = 0.324$, and $\zeta = 0.547$.

These calculations, summarised in Table 10.7, demonstrate that quite substantial reductions occur in both the axial force and power output as a result of including the Prandtl tip loss correction factor. ■

10.9 ROTOR CONFIGURATIONS

Clearly, with so many geometric design and operational variables to consider, it is not easy to give general rules about the way performance of a wind turbine will be effected by the values of parameters other than (perhaps) running large numbers of computer calculations. The variables for the turbine include the number of blades, blade solidity, blade taper and twist, as well as tip-speed ratio.

Blade Planform

In all the preceding worked examples a constant value of chord size was used, mainly to simplify proceedings. The actual planform used for the blades of most HAWTs is tapered, the degree of taper is

chosen for structural, economic, and, to some degree, aesthetic reasons. If the planform is known or one can be specified, the calculation procedure developed previously, i.e., the BEM method, can be easily modified to include the variation of blade chord as a function of radius.

In a following section, Glauert's analysis is extended to determine the variation of the rotor blade planform under *optimum conditions*.

Effect of Varying the Number of Blades

A first estimate of overall performance (power output and axial force) based on actuator disc theory was given earlier. The choice of the number of blades needed is one of the first items to be considered. Wind turbines have been built with anything from 1 to 40 blades. The vast majority of HAWTs, with high tip-speed ratios, have either two or three blades. For purposes such as water pumping, rotors with low tip-speed ratios (giving high starting torques) employ a large number of blades. The chief considerations to be made in deciding on the blade number, Z , are the design tip-speed ratio, J , the effect on the power coefficient, C_P , as well as other factors such as weight, cost, structural dynamics, and fatigue life, which we cannot consider in this short chapter.

Tangler (2000) has reviewed the evolution of the rotor and the design of blades for HAWTs, commenting that, for large commercial machines, the upwind, three-bladed rotor is the industry accepted standard. Most large machines built since the mid-1990s are of this configuration. The blade number choice appears to be guided mainly by inviscid calculations presented by Rohrbach and Worobel (1977) and Miller, Dugundji et al. (1978). Figure 10.16 shows the effect on the power coefficient C_P of blade number for a range of tip-speed ratio, J . It is clear, on the basis of these results, that there is a significant increase in C_P in going from one blade to two blades, rather less gain in going from two to three blades, and so on for higher numbers of blades. In reality, the apparent gains in C_P would be quickly cancelled when blade frictional losses are included with more than two or three blades.

Tangler (2000) indicated that considerations of rotor noise and aesthetics strongly support the choice of three blades rather than two or even one. Also, for a given rotor diameter and solidity, a three-bladed rotor will have two thirds the blade loading of a two-bladed rotor resulting in lower impulsive noise generation.

Effect of Varying Tip-Speed Ratio

The tip-speed ratio J is generally regarded as a parameter of some importance in the design performance of a wind turbine. So far, all the examples have been determined with one value of J and it is worth finding out how performance changes with other values of the tip-speed ratio. Using the procedure outlined in Example 10.6, assuming zero drag ($\varepsilon = 0$) and ignoring the correction for a finite number of blades, the overall performance (axial force and power) has been calculated for $C_L = 0.6$, 0.8, and 1.0 (with $l = 1.0$) for a range of J values. Figure 10.17 shows the variation of the axial force coefficient C_X plotted against J for the three values of C_L and Figure 10.18 the corresponding values of the power coefficient C_P plotted against J . A point of particular interest is that when C_X is replotted as $C_X/(JC_L)$ all three sets of results collapse onto one straight line, as shown in Figure 10.19. The main interest in the axial force would be its effect on the bearings and on the supporting structure of the turbine rotor. A detailed discussion of the effects of both steady and unsteady loads acting on the rotor blades and supporting structure of HAWTs is given by Garrad (1990).

**FIGURE 10.16**

Theoretical Effect of Tip-Speed Ratio and Number of Blades on Power Coefficient Assuming Zero Drag

**FIGURE 10.17**

Variation of the Axial Force Coefficient C_x versus Tip-Speed Ratio J for Three Values of the Lift Coefficient $C_L = 0.6, 0.8$, and 1.0

**FIGURE 10.18**

Variation of the Power Coefficient C_P versus J for Three Values of the Lift Coefficient $C_L = 0.6, 0.8$, and 1.0

**FIGURE 10.19**

Axial Force Coefficient Divided by $J C_L$ and Plotted versus J (This Collapses All Results Shown in Figure 10.17 onto a Straight Line)

Note: The range of these calculated results is effectively limited by the non-convergence of the value of the axial flow induction factor a at, or near, the blade tip at high values of J . The largeness of the blade loading coefficient, $\lambda = ZlC_L/(8\pi r)$, is wholly responsible for this non-convergence of a . In practical terms, λ can be reduced by decreasing C_L or by reducing l (or by a combination of these). Also, use of the tip correction factor in calculations will extend the range of J for which convergence of a can be obtained. The effect of any of these measures will be to reduce the amount of power developed. However, in the examples throughout this chapter, to make valid comparisons of performance the values of lift coefficients and chord are fixed. It is of interest to note that the curves of the power coefficient C_P all rise to about the same value, approximately 0.48, where the cutoff due to non-convergence occurs.

Rotor Optimum Design Criteria

Glauert's momentum analysis provides a relatively simple yet accurate framework for the preliminary design of wind turbine rotors. An important aspect of the analysis not yet covered was his development of the concept of the "ideal windmill" that provides equations for the optimal rotor. In a nutshell, the analysis gives a preferred value of the product $C_L l$ for each rotor blade segment as a function of the local speed ratio j defined by

$$j = \frac{\Omega r}{c_{x1}} = \left(\frac{r}{R}\right)J. \quad (10.49)$$

By choosing a value for either C_L or l enables a value for the other variable to be determined from the known optimum product $C_L l$ at every radius.

The analysis proceeds as follows. Assuming $C_D = 0$, we divide eqn. (10.36b) by eqn. (10.35b) to obtain

$$\frac{a'(1-a)}{a(1+a')} = \tan^2 \phi. \quad (10.50)$$

Also, from eqns. (10.39) and (10.49), we have

$$\tan \phi = \frac{(1-a)}{j(1+a')}. \quad (10.51)$$

We now substitute for $\tan \phi$ in eqn. (10.50) to obtain

$$\frac{1}{j^2} = \frac{a'(1+a')}{a(1-a)}. \quad (10.52)$$

Thus, at any radius r , the value of j is constant for a fixed tip-speed ratio J , and the right-hand side is likewise constant. Looking again at eqn. (10.17), for specific values of c_{x1} and Ω , the power output is a maximum when the product $(1-a)a'$ is a maximum. Differentiating this product and setting the result to zero, we obtain

$$a' = \frac{da'}{da}(1-a). \quad (10.53)$$

From eqn. (10.52), after differentiating and some simplification, we find

$$j^2(1 + 2a') \frac{da'}{da} = 1 - 2a. \quad (10.54)$$

Substituting eqn. (10.53) into eqn. (10.54) we get

$$j^2(1 + 2a')a' = (1 - 2a)(1 - a).$$

Combining this equation with eqn. (10.52) we obtain

$$\frac{1 + 2a'}{1 + a'} = \frac{1 - 2a}{a}.$$

Solving this equation for a' ,

$$a' = \frac{1 - 3a}{4a - 1}. \quad (10.55)$$

Substitute eqn. (10.55) back into eqn. (10.52) and using $1 + a' = a/(4a - 1)$, we get

$$a'j^2 = (1 - a)(4a - 1). \quad (10.56)$$

Equations (10.53) and (10.55) can be used to determine the variation of the interference factors a and a' with respect to the coordinate j along the turbine blade length. After combining eqn. (10.55) with (10.56) we obtain

$$j = (4a - 1) \sqrt{\frac{1 - a}{1 - 3a}}. \quad (10.57)$$

Equation (10.57), derived for these ideal conditions, is valid only over a very narrow range of a , i.e., $\frac{1}{4} < a < \frac{1}{3}$. It is important to keep in mind that optimum conditions are much more restrictive than general conditions. Table 10.8 gives the values of a' and j for increments of a in this range (as well as ϕ and λ). It will be seen that for large values of j the interference factor a is only slightly less than $\frac{1}{3}$ and a' is very small. Conversely, for small values of j the interference factor a approaches the value $\frac{1}{4}$ and a' increases rapidly.

Table 10.8 Relationship Between a' , a , ϕ , j , and λ at Optimum Conditions

a	a'	j	ϕ (deg)	λ
0.260	5.500	0.0734	57.2	0.4583
0.270	2.375	0.157	54.06	0.4131
0.280	1.333	0.255	50.48	0.3637
0.290	0.812	0.374	46.33	0.3095
0.300	0.500	0.529	41.41	0.2500
0.310	0.292	0.753	35.33	0.1842
0.320	0.143	1.150	27.27	0.1111
0.330	0.031	2.63	13.93	0.0294
0.333	0.003	8.574	4.44	0.0030

The flow angle ϕ at optimum power conditions is found from eqns. (10.50) and (10.55),

$$\tan^2 \phi = \frac{a'(1-a)}{a(1+a')} = \frac{(1-3a)(1-a)}{a^2},$$

therefore,

$$\tan \phi = \frac{1}{a} \sqrt{(1-3a)(1-a)}. \quad (10.58)$$

Again, at optimum conditions, we can determine the blade loading coefficient λ in terms of the flow angle ϕ . Starting with eqn. (10.55), we substitute for a' and a using eqns. (10.36b) and (10.35b). After some simplification we obtain

$$\lambda^2 = \sin^2 \phi - 2\lambda \cos \phi.$$

Solving this quadratic equation we obtain a relation for the optimum blade loading coefficient as a function of the flow angle ϕ ,

$$\lambda = 1 - \cos \phi \equiv \frac{ZIC_L}{8\pi r}. \quad (10.59)$$

Returning to the general conditions, from eqn. (10.51) together with eqns. (10.35b) and (10.36b), we obtain

$$\tan \phi = \frac{1(1-a)}{j(1+a')} = \frac{1}{j} \left(\frac{a}{a'} \right) \tan^2 \phi,$$

therefore,

$$j = \left(\frac{a}{a'} \right) \tan \phi. \quad (10.60)$$

Rewriting eqns. (10.35b) and (10.36b) in the form

$$\frac{1}{a} = 1 + \frac{1}{\lambda} \sin \phi \tan \phi \quad \text{and} \quad \frac{1}{a'} = \frac{1}{\lambda} \cos \phi - 1$$

and substituting into eqn. (10.60) we get

$$j = \sin \phi \left(\frac{\cos \phi - \lambda}{\lambda \cos \phi + \sin^2 \phi} \right). \quad (10.61)$$

Reintroducing optimum conditions with eqn. (10.59),

$$j = \frac{\sin \phi (2 \cos \phi - 1)}{(1 - \cos \phi) \cos \phi + \sin^2 \phi},$$

therefore,

$$j = \frac{\sin \phi (2 \cos \phi - 1)}{(1 + 2 \cos \phi)(1 - \cos \phi)}, \quad (10.62)$$

$$j\lambda = \frac{\sin \phi (2 \cos \phi - 1)}{1 + 2 \cos \phi}. \quad (10.63)$$

Some values of λ are shown in Table 10.8. Equation (10.62) enables j to be calculated directly from ϕ . These equations also allow the optimum blade layout in terms of the product of the chord l and the lift coefficient C_L (for $C_D = 0$) to be determined. By ascribing a value of C_L at a given radius the corresponding value of l can be determined.

Example 10.10

A three-bladed HAWT, with a 30 m tip diameter, is to be designed for optimum conditions with a constant lift coefficient C_L of unity along the span and with a tip-speed ratio $J = 5.0$. Determine a suitable chord distribution along the blade, from a radius of 3 m to the blade tip, satisfying these conditions.

Solution

It is obviously easier to input values of ϕ to determine the values of the other parameters than attempting the reverse process. To illustrate the procedure, choose $\phi = 10^\circ$, and so we determine $j\lambda = 0.0567$, using eqn. (10.63). From eqn. (10.59) we determine $\lambda = 0.0152$ and then find $j = 3.733$. Now

$$j = \frac{\Omega r}{c_{x1}} = J \left(\frac{r}{R} \right) = \frac{5}{15} r,$$

$$r = 3j = 11.19 \text{ m.}$$

As

$$j\lambda = J \left(\frac{r}{R} \right) = \frac{ZlC_L}{8\pi r} = \frac{J ZlC_L}{R 8\pi} = \frac{l}{8\pi},$$

after substituting $J = 5$, $R = 15$ m, $Z = 3$, $C_L = 1.0$. Thus,

$$l = 8\pi \times 0.0567 = 1.425 \text{ m}$$

and Table 10.9 shows the optimum blade chord and radius values.

Figure 10.20 shows the calculated variation of blade chord with radius. The fact that the chord increases rapidly as the radius is reduced would suggest that the blade designer would ignore optimum conditions at some point and accept a slightly reduced performance. A typical blade planform (for the Micon 65/13 HAWT; Tangler et al. 1990) is also included in this figure for comparison.

Table 10.9 Values of Blade Chord and Radius (Optimum Conditions)

ϕ (deg)	j	$4j\lambda$	r (m)	l (m)
30	1.00	0.536	3.0	3.368
20	1.73	0.418	5.19	2.626
15	2.42	0.329	7.26	2.067
10	3.733	0.2268	11.2	1.433

2.0	0.865	0.512	10.0	0.987	0.584

10.10 THE POWER OUTPUT AT OPTIMUM CONDITIONS

Equation (10.17) expresses the power output under general conditions, i.e., when the rotational interference factor a' is retained in the analysis. From this equation the power coefficient can be written as

$$C_P = P / \left(\frac{1}{2} \pi \rho R^2 c_{x1}^3 \right) = \frac{8}{J^2} \int_{j_h}^J (1 - a) a' j^3 dj.$$

This equation converts to optimum conditions by substituting eqn. (10.56) into it, i.e.,

$$C_P = \frac{8}{J^2} \int_{j_h}^J (1 - a)^2 (4a - 1) j dj. \quad (10.64)$$

where the limits of the integral are changed to j_h and $J = \Omega R / c_{x1}$. Glauert (1935) derived values for C_P for the limit range $j = 0$ to J (from 0.5 to 10) by numerical integration and the relative maximum power coefficient ζ . These values are shown in Table 10.10. So, to obtain a large fraction of the possible power it is apparent that the tip-speed ratio J should not be too low.

10.11 HAWT BLADE SECTION CRITERIA

The essential requirements of turbine blades clearly relate to aerodynamic performance, structural strength and stiffness, ease of manufacture, and ease of maintenance in that order. It was assumed, in the early days of turbine development, that blades with high lift and low drag were the ideal choice with the result that *standard* aerofoils, e.g., NACA 44XX, NACA 230XX, (where the XX denotes thickness to chord ratio, as a percentage), suitable for aircraft were selected for wind turbines. The aerodynamic characteristics and shapes of these aerofoils are summarised by Abbott and von Doenhoff (1959).

The primary factor influencing the lift–drag ratio of a given aerofoil section is the Reynolds number. The analysis developed earlier showed that optimal performance of a turbine blade depends on the product of blade chord and lift coefficient, lC_L . When other turbine parameters such as the tip–speed ratio J and radius R are kept constant, the operation of the turbine at a high value of C_L thus allows the use of narrower blades. Using narrower blades does not necessarily result in lower viscous losses, instead the lower Reynolds number often produces higher values of C_D . Another important factor to consider is the effect on the blade structural stiffness, which decreases sharply as thickness decreases. The standard aerofoils just mentioned also suffered from a serious fault; namely, a gradual performance degradation from roughness effects consequent on leading-edge contamination. Tangler commented that “the annual energy losses due to leading-edge roughness are greatest for *stall-regulated*³ rotors.” Figure 10.21, adapted from Tangler et al. (1990) illustrates the surprising loss in power output of a stall-regulated, three-bladed rotor on a medium scale (65 kW) turbine. The loss in performance is proportional to the reduction in maximum lift coefficient along the blade. The roughness also degrades the aerofoil’s lift-curve slope and increases profile drag, further contributing to losses. Small scale wind turbines are even more severely affected because their lower elevation allows the accretion of more

FIGURE 10.21

³Refer to Section 10.13, Control Methods.

insects and dust particles and the debris thickness is actually a larger fraction of the leading-edge radius. Some details of the effect of blade fouling on a small scale (10 m diameter) rotor are given by Lissaman (1998). Estimates of the typical annual energy loss (in the United States) caused by this increased roughness are 20–30%. The newer NREL turbine blades described in the next section are much less susceptible to the effects of fouling.

10.12 DEVELOPMENTS IN BLADE MANUFACTURE

Snel (1998) remarked, “in general, since blade design details are of a competitive nature, not much information is present in the open literature with regard to these items.” Fortunately, for progress, efficiency, and the future expansion of wind energy power plants, the progressive and enlightened policies of the U.S. Department of Energy, NASA, and the National Renewable Energy Laboratory allowed the release of much valuable knowledge to the world concerning wind turbines. Some important aspects gleaned from this absorbing literature follows.

Tangler and Somers (1995) outlined the development of special-purpose aerofoils for HAWTs, which began as a collaborative venture between the National Renewable Energy Laboratory (NREL) and Airfoils Incorporated. Seven families of blades comprising 23 aerofoils were planned for rotors of various sizes. These aerofoils were designed to have a maximum C_L that was largely insensitive to roughness effects. This was achieved by ensuring that the boundary layer transition from laminar to turbulent flow on the suction surface of the aerofoil occurred very close to the leading edge, just before reaching the maximum value of C_L . These new aerofoils also have low values of C_D in the clean condition because of the extensive laminar flow over them. The tip-region aerofoils typically have close to 50% laminar flow on the suction surface and over 60% laminar flow on the pressure surface.

The preferred choice of blade from the NREL collection of results rather depends on whether the turbine is to be regulated by stall, by variable blade pitch or by variable rotor speed. The different demands made of the aerofoil from the hub to the tip preclude the use of a single design type. The changing aerodynamic requirements along the span are answered by specifying different values of lift and drag coefficients (and, as a consequence, different aerofoil sections along the length). For stall-regulated turbines, a limited maximum value of C_L in the blade tip region is of benefit to passively control peak rotor power. Figures 10.22 to 10.25 show families of aerofoils for rotors originally designated as “small-, medium-, large-, and very large-sized” HAWTs,⁴ designed specifically for turbines having low values of maximum blade tip C_L . A noticeable feature of these aerofoils is the substantial thickness–chord ratio of the blades, especially at the root section, needed to address the structural requirements of “flap stiffness” and the high root bending stresses.

According to Tangler (2000) the evolutionary process of HAWTs is not likely to deviate much from the now firmly established three-bladed, upwind rotors, which are rapidly maturing in design. Further refinements, however, can be expected of the various configurations and the convergence towards the best of the three options of stall-regulated, variable-pitch, and variable-speed blades. Blades on large,

⁴With the top end size of HAWTs growing ever larger with time, the size categories of “large” or “very large” used in the 1990s are rather misleading and, perhaps, better described by stating either the relevant diameter or power range.

stall-regulated wind turbines with movable speed control tips may be replaced by variable-pitch blades for more refined peak power control and reliability.

With the very large HAWTs [i.e., 104 m diameter, refer to Figure 10.4(a)] being brought into use, new blade section designs and materials will be needed. Mason (2004) has described “lightweight” blades being made from a carbon/glass fibre composite for the 125 m diameter, 5 MW HAWT to be deployed in the North Sea as part of Germany’s first deepwater off-shore project.

10.13 CONTROL METHODS (STARTING, MODULATING, AND STOPPING)

Referring to Figure 10.9, the operation of a wind turbine involves starting the turbine from rest, regulating the power while the system is running, and stopping the turbine if and when the wind speed becomes excessive. Startup of most wind turbines usually means operating the generator as a motor to overcome initial resistive torque until sufficient power is generated at “cut-in” speed assuming, of course, that a source of power is available.

Blade Pitch Control

The angle of the rotor blades is actively adjusted by the machine control system. This, known as *blade pitch control*, has the advantage that the blades have built-in braking, which brings the blades to rest. Pitching the whole blade requires large actuators and bearings, increasing the weight and expense of

the system. One solution to this problem is to use *partial span blade pitch control* where only the outer one third of the blade span is pitched.

Passive or Stall Control

The aerodynamic design of the blades (i.e., the distribution of the twist and thickness along the blade length) varies in such a way that blade stall occurs whenever the wind speed becomes too high. The turbulence generated under stall conditions causes less energy to be transferred to the blades minimizing the output of power at high wind speeds.

According to Armstrong and Brown (1990) there is some competition between the advocates of the various systems used in commercial wind farms. The classical European machines are usually stall regulated, while most American designs are now either pitch regulated or, for large turbines, use some form of aileron control.

Aileron Control

Aerodynamic control surfaces have been investigated by the U.S. DOE and NASA as an alternative to full blade-pitch control. The aileron control system has the potential to reduce cost and weight of the rotors of large HAWTs. The control surfaces consist of a moveable flap built into the outer part of the trailing edge of the blade, as shown in Figure 10.26(a). Although they appear similar to the flaps and ailerons used on aircraft wings, *they operate differently*. Control surfaces on an aircraft wing deflect downwards towards the high-pressure surface in order to increase lift during takeoff and landing, whereas on a wind turbine blade the flaps deflect towards the low-pressure surface (i.e., downwind side) *to reduce lift and cause a braking effect*. Figure 10.26(b) shows sketches of two typical control surface arrangements in the fully deflected position, included in a paper by Miller and Sirocky (1985). The configuration marked *plain* was found to have the best braking performance. The configuration

marked *balanced* has both a low pressure and a high pressure control surface, which helps to reduce the control torque.

Ailerons change the lift and drag characteristics of the basic blade aerofoil as a function of the deflection angle. Full-scale field tests were conducted on the Mod-O wind turbine⁵ with ailerons of 20% chord and 38% chord. Results from loss of load to shutdown showed that the 38% chord ailerons were the better aerodynamic braking device than the 20% chord ailerons. Also, the 38% chord ailerons effectively regulated the power output over the entire operating range of the Mod-O turbine. Figure 10.27 shows the variation of the lift and drag coefficients for the 38% chord ailerons set at 0° , -60° , and -90° .

Although wind tunnel tests normally present results in terms of lift and drag coefficients, Miller and Sirocky (1985) wisely chose to represent their aileron-controlled wind turbine results in terms of a

⁵Details of the Mod-O wind turbine are given in Divone (1998).

**FIGURE 10.28**

Effect of Chord Length on Chordwise Force Coefficient, C_C , for a Range of Angles of Attack. (Adapted from Snyder et al., 1984, Unpublished)

chordwise force coefficient, C_C (also called a *suction coefficient*). C_C is a combination of both the lift and drag coefficients, as described next:

$$C_C = C_L \sin \alpha - C_D \cos \alpha, \quad (10.65)$$

where α = angle of attack.

The reason for using C_C to describe aileron-control braking effectiveness is that only the chordwise force produces torque (assuming a wind turbine blade with no pitch or twist). Because of this direct relationship between chordwise force and rotor torque, C_C serves as a convenient parameter for evaluating an aileron's braking effectiveness. Thus, if C_C is negative it corresponds to a negative torque producing a rotor deceleration. Clearly, it is desirable to have a negative value of C_C available for all angles of attack. Figure 10.28 shows some experimental results, Snyder, Wentz, and Ahmed (1984), illustrating the variation of the chordwise force coefficient with the angle of attack, α , for aileron percent chord of 20 and 30% for several aileron deflection angles. The general conclusions to be drawn from these results is that increasing the aileron chord length and the aileron deflection angle contribute to better aerodynamic braking performance.

10.14 BLADE TIP SHAPES

The blade geometry determined with various aerodynamic models gives no guidance of an efficient aerodynamic tip shape. From a basic view of fluid mechanics, a strong shed vortex occurs at the blade tip as a result of the termination of lift and this together with the highly three-dimensional nature of the flow at the blade tip causes a loss of lift. The effect is exacerbated with a blunt blade end as this increases the intensity of the vortex.

Many attempts have been made to improve the aerodynamic efficiency by the addition of various shapes of "winglet" at the blade ends. Details of field tests on a number of tip shapes intended to

**FIGURE 10.29**

Blade Tip Geometries (Tangler, 2000; Courtesy NREL)

improve performance by controlling the shedding of the tip vortex are given by Gyatt and Lissaman (1985). According to Tangler (2000), test experience has shown that rounding the leading-edge corner, Figure 10.29, with a contoured, streamwise edge (a swept tip) yields good performance. Tip shapes of other geometries are widely used. The sword tip also shown is often chosen because of its low noise generation, *but this is at the expense of a reduction in performance.*

10.15 PERFORMANCE TESTING

Comparison and improvement of aerodynamic predictive methods for wind turbine performance and field measurements have many inherent limitations. The natural wind is capricious; it is unsteady, non-uniform, and variable in direction, making the task of interpreting performance measurements of questionable value. As well as the non-steadiness of the wind, non-uniformity is present at all elevations as a result of wind shear, the vertical velocity profile caused by ground friction. The problem of obtaining accurate, measured, steady state flow conditions for correlating with predictive methods was solved by testing a full-size HAWT in the world's largest wind tunnel, the NASA Ames low speed wind tunnel⁶ with a test section of 24.4 m × 36.6 m (80 × 120 ft).

10.16 PERFORMANCE PREDICTION CODES

Blade Element Theory

The BEM theory presented, because of its relative simplicity, has been the mainstay of the wind turbine industry for predicting wind turbine performance. Tangler (2002) has listed some of the many versions

⁶Further details of this facility can be found at windtunnels.arc.nasa.gov/80ft1.html.

of performance prediction codes based upon the BEM theory and reference to these is shown in the following table:

Table 10.11	
Code Name	Reference
PROP	Wilson and Walker (1976)
PROP93	McCarty (1993)
PROPID	Selig and Tangler (1995)
WTPERF	Buhl (2000)

According to Tangler (2002), some limitations are apparent in the BEM theory that affect its accuracy and are related to simplifications that are not easily corrected. Basically, these errors begin with the assumption of uniform inflow over each annulus of the rotor disc and no interaction between annuli. Also, the tip loss model accounts for blade number effects but not effects due to differences in blade planform.

Lifting Surface, Prescribed Wake Theory

Modelling the rotor blades with a lifting surface and its resulting vortex wake is claimed to eliminate the errors resulting from the simplifications mentioned for the BEM theory. The lifting surface, prescribed wake theory (LSWT) is an advanced code capable of modelling complex blade geometries and, according to Kocurek (1987), allows for wind shear velocity profiles, tower shadow, and off-axis operation. Performance predictions are calculated by combining the lifting surface method with blade element analysis that incorporates two-dimensional aerofoil lift and drag coefficients as functions of the angle of attack and the Reynolds number.

It is not possible to pursue the ramifications of this developing theory any further in this introductory text. Gerber et al. (2004) give a useful, detailed description of LSWT methodology and suggestions for its likely future development. Other leading references that give details of LSWT theory are Kocurek (1987) and Fisichella (2001).

Comparison with Experimental Data

A HAWT with a 10 m diameter rotor was comprehensively tested by NREL in the NASA Ames wind tunnel. Some of these test results are reported by Tangler (2002) and only a brief extract comparing the predicted and measured power is given here. The test configuration comprised a constant speed (72 rpm), two-bladed rotor, which was upwind and stall regulated. Rotor blades (see Giguere and Selig, 1998) for this test had a linear chord taper with a non-linear twist distribution, as shown in Figure 10.30. It operated with -3° tip pitch relative to the aerofoil chord line. The S809 aerofoil was used from blade root to tip for simplicity and because of the availability of two-dimensional wind tunnel data for the blade section.

Comparison of the measured power output with the BEM (WTPERF and PROP93) and the LSWT predictions are shown in Figure 10.31, plotted against wind speed. At low wind speeds, up to about 8 m/s, both the BEM and LSWT predictions are in very good agreement with the measured results. At higher wind speeds both theoretical methods slightly underpredict the power actually measured, the LSWT method rather more than the BEM method. It may be a matter of interpretation but it appears

**FIGURE 10.30**

Rotor Blade Tested in the NASA Ames Wind Tunnel Showing the Chord and Twist Distributions (Tangler, 2002; Courtesy NREL)

to this writer that only after blade stall (when the measured power sharply decreases) does the LSWT method approach closer to the measured power than the BEM method. Thus, the overall result obtained from wind tunnel measurements appears, in general, to strongly confirm the validity of the BEM theory prior to the onset of stall.

Peak and Post-Peak Power Predictions

The comprehensive testing of a highly instrumented 10 m rotor in the NASA Ames 24.4×36.6 m wind tunnel has provided steady state data that gives better understanding of the complex phenomena of blade stall. Until recently, according to Gerber et al. (2004), peak and post-peak power were mistakenly thought to coincide with blade stall that originated in the root region and propagated towards the tip with increased wind speed. This rather simplistic scenario does not occur due to three-dimensional *delayed stall* effects. Analysis of some of the more recent data, Tangler (2003), showed leading edge separation to occur in the mid-span region, which spread radially inwards and outwards with increased wind speed. The BEM approach lacks the ability to model the three-dimensional stall process. Further efforts are being made to take these real effects into account.

10.17 ENVIRONMENTAL CONSIDERATIONS

On what may be classed as environmental objections are the following topics, arguably in decreasing order of importance: (i) visual intrusion, (ii) acoustic emissions, (iii) impact on local ecology, (iv) land usage, and (v) effects on radio, radar, and television reception. Much has been written about all these

FIGURE 10.31

Measured Power Output (kW) (CER/NASA) for the 10 m Diameter Wind Turbine versus Wind Speed (m/s) Compared with Theoretical Predictions (Tangler, 2002; Courtesy NREL)

topics, also numerous websites cover each of them so, for brevity, only a brief recapitulation of some of the main issues regarding the first two are afforded any space in this chapter.

Visual Intrusion

The matter of public acceptance (in the United Kingdom and several other countries) is important and clearly depends upon where the turbines are located and their size. The early investigations of acceptability indicated that the sight of just a few turbines, perhaps a mile or so distant, produced only a few isolated complaints and even appeared to generate some favourable interest from the public. However, any suggestion of locating wind turbines on some nearby *scenic* hillside produced rather strong opposition, comments in the press, and the formation of groups to oppose the proposals. The opposition set up by a few vociferous landowners and members of the public in the 1990s retarded the installation of wind farms for several years in many parts of the United Kingdom. However, wind turbines in larger numbers located in relatively remote upland areas and not occupying particularly scenic ground have been installed. Nowadays, medium- and large-size wind turbines in small numbers (i.e., 20 to 30) are regarded as beneficial to the community, providing they are not too close. Perhaps they may eventually become tourist attractions in the area. The graceful, almost hypnotic turning of the slender blades of the larger turbines, seemingly in slow motion, has generally led to a more positive aesthetic reaction, in most surveys. Other factors can importantly sway public acceptance of wind turbines. The first factor

is the perceived benefit to the community with part or total ownership, giving lower power costs and possibly even preferential availability of power. The second factor comes from the amount of careful planning and cooperation between the installers and the leaders of the community long before any work on installation commences. It is a strange fact that the old-fashioned, disused windmills, now local landmarks, that abound in many parts of Europe (e.g., see Figure 10.2), are now widely accepted.

Acoustic Emissions

Wind turbines undoubtedly generate some noise but, with the improvements in design in recent years, the level of noise emitted by them has dropped remarkably.

Aerodynamic broadband noise is typically the largest contributor to wind turbine noise. The main efforts to reduce this noise have included the use of lower blade tip speeds, lower blade angles of attack, upwind turbine configuration, variable speed operation, and specially modified blade trailing edges and tip shapes. For the new, very large (i.e., 1–5 MW size) wind turbines the rotor tip speed on land is limited (in the United States the limit is 70 m/s). However, large variable speed wind turbines often rotate at lower tip speeds in low speed winds. As wind speed increases, the rotor speed is allowed to increase until the limit is reached. This mode of operation results in much quieter working at low wind speeds than a comparable constant speed wind turbine.

The study of noise emitted by wind turbines is a large and complex subject. No coverage of the basic theory is given in this chapter. Numerous publications on acoustics are available and one particularly recommended as it covers the study of fundamentals to some extent is the white paper by Rogers and Manwell (2004), prepared by NREL. A wide ranging, deeper approach to turbine noise is given in the NASA/DOE publication “Wind Turbine Acoustics,” by Hubbard and Shepherd (1990).

A particular problem occurs in connection with small wind turbines. These turbines are sold in large numbers in areas remote from electric utilities and are often installed close to people’s homes, often too close. There is an urgent need for reliable data on the levels of noise generated so that homeowners and communities can then reliably anticipate the noise levels from wind turbines prior to installation. The NREL have performed acoustic tests (Migliore, van Dam, and Huskey 2004) on eight small wind turbines with power ratings from 400 W to 100 kW to develop a database of acoustic power output of new and existing turbines and to set targets for low noise rotors. Test results will be documented as NREL reports, technical papers, seminars, colloquia, and on the Internet. In comparing the results, Migliore et al. reported that, following improvements to the blading, the noise from the Bergey Excel [see Figure 10.4(b)] was reduced to the point that the turbine noise could not be separated from the background noise. As a result any further testing will need to be done in a much quieter location.

The Largest Wind Turbine

Claims are sometimes made that a new wind turbine is the biggest yet and produces more power than any other. Such claims need to be carefully considered and compared with verified performance data. The latest claimant for the title of “largest wind turbine” is reported as the Enercon E-126, a 3-bladed rotor of 126 m diameter and officially rated at 6 MW. The hub height was not stated. This could be an important factor. From scale measurements of a photograph the height appears to be 138.6 m.

The previous record holder was the 5 MW REpower Systems wind turbine installed at Brunsbüttel in Schleswig-Holstein, Germany (October 1, 2004), according to a report in *Renewable Energy World*

(November–December 2004). The three-bladed rotor again has a tip diameter of 126.3 m (blade length 61.5 m, maximum chord 4.6 m) and a hub height of 120 m.

The various speeds and rotor speed range quoted (data that may be useful in problem solving) are

Rotor speed	6.9–12.1 rev/min
Rated wind speed	13 m/s
Cut-in wind speed	3.5 m/s
Cut-out wind speed	25 m/s (onshore); 30 m/s (offshore)

The chief factors that influence the higher output of the Enerco E-126 turbine seems to be the increased hub height and the possibly windier location of the site.

PROBLEMS

1. The original 5 MW, three-bladed HAWT, made by RE Systems has a tip diameter of 126.3 m and a rated wind speed of 13 m/s. The cut-in wind speed was 3.5 m/s and the onshore cut-out wind speed is 25 m/s. Determine the rated value of the power coefficient C_p and compare this with the value at the Betz limit. Assume the air density $\rho = 1.2 \text{ kg/m}^3$.
2. For the preceding problem, using actuator disc theory, determine the *axial flow induction factor*, \bar{a} , and the static pressure difference across the disc at the rated wind speed.
3. A horizontal axis wind turbine with a hub height of 80 m and blades of 80 m diameter develops 1.824 MW in a wind of 12 m/s with a blade tip-speed ratio of 4.5. Determine
 - (a) the power coefficient, the relative maximum power coefficient, and the rotational speed;
 - (b) for the same wind speed at 80 m height the wind speed that could be expected at a height of 150 m and, if the hub height was raised to that level, the likely power output if the power coefficient remains the same.Assume the density is constant at 1.2 kg/m^3 and that the one-seventh power law applies.
4. A three-bladed HAWT with a rotor of 60 m diameter operates with a tip-speed ratio, $J = 5.5$. At a radius of 25 m the blade chord is 1.5 m and the blade pitch angle, $\beta = 2.5^\circ$. Assuming negligible drag and using an iterative method of calculation, determine values for the axial and tangential induction factors a and a' at that section. Assuming that C_L is $0.1 \times$ angle of incidence, what is the final value of the lift coefficient?

Appendix A: Preliminary Design of an Axial Flow Turbine for a Large Turbocharger

Turbochargers are used to increase the power output of internal combustion engines by compressing the air prior to it being admitted into the engine. This is achieved by employing a centrifugal compressor driven by a turbine that is powered by the engine exhaust gases. Figure A.1 shows the mechanical arrangement with the compressor and turbine on a common shaft. An air or water cooler is often used to reduce the temperature of the air entering the engine, enabling greater power to be achieved by the engine.

There are two basic types of turbocharger:

- (i) small units for turbocharging the complete range of automobiles and trucks that incorporate an *inward flow radial turbine*;
- (ii) large units whose duties include ship propulsion and electrical power generation, typically 1 MW and above, employ an *axial-flow turbine*. The present design study is directed to this larger size of unit. The essential design philosophy of these larger turbochargers is that they have high efficiencies over a limited flow range unlike the automotive turbochargers, which usually have a rather lower efficiency over a wide flow range. All turbochargers need to be compact, durable, and have low unit cost. Typically, for these large units, low unit cost is maintained by using single-stage turbines even for pressure ratios greater than 4.5 to 1.

Detailed discussions of the various types and design features of turbochargers are given by Flaxington and Swain (1999) and by Iwaki and Mitsubori (2004).

DESIGN REQUIREMENTS

The total pressure available at turbine inlet,	2.1 kPa
The static pressure at turbine exit, p_3 ,	1.05 kPa
Entry temperature of products of combustion to turbine, T_{01} ,	500°C
Mass flow rate, \dot{m}	8 kg/s
Free vortex design	
Reaction ratio, R ,	0.4
Flow coefficient, ϕ ,	0.4
Axial flow at entry and exit of turbine	
Target efficiency, η_{tr} ,	0.90
Assume a constant value of specific heat at constant pressure, C_p (kJ/kg°C),	1.178
Assume a ratio of specific heats, γ ,	1.32

**FIGURE A.1**

The Mechanical Arrangement of the Centrifugal Compressor and Axial-flow Turbine of a Large Turbocharger (With Permission of ABB Asea Brown Boveri)

MEAN RADIUS DESIGN

The steps in a preliminary design of an axial flow turbine are essentially a process of trial and error and several different approaches are possible depending on the data available, any additional assumptions that may have to be made, and the designer's previous experience. The notation used relates to that of Figure 4.4.

First we need to determine the isentropic enthalpy drop across the stage, $\Delta h_{is} = h_{01} - h_{3ss}$.

The isentropic temperature ratio is

$$\frac{T_{3ss}}{T_{01}} = \left(\frac{p_3}{p_{01}} \right)^{(\gamma-1)/\gamma} = 0.5^{0.2424} = 0.8453.$$

Therefore,

$$\Delta h_{is} = C_p T_{01} (1 - T_{3ss}/T_{01}) = 1.178 \times 773 \times (1 - 0.8453) = 140.8 \text{ kJ/kg}$$

and

$$T_{3ss} = 653.4 \text{ K.}$$

From Figure 4.4, $\Delta W = h_{01} - h_{03}$ and the total-to-total efficiency can be written as

$$\eta_{tt} = \frac{\Delta W}{h_{01} - h_{03ss}} \approx \frac{\Delta W}{h_{01} - h_{3ss} - \frac{1}{2}c_3^2},$$

using the small approximation, $\frac{1}{2}c_3^2 \approx \frac{1}{2}c_{3ss}^2$. Hence,

$$\Delta h_{is} = \frac{\Delta W}{\eta_{tt}} + \frac{1}{2}c_3^2 = \frac{\Delta W}{\eta_{tt}} + \frac{1}{2}c_x^2.$$

From eqn. (4.13a) and with $\alpha_1 = 0$ (axial entry flow),

$$R = 1 - \frac{c_x \tan \alpha_2}{2U}; \quad (\text{A.1})$$

therefore,

$$\Delta W = U c_x \tan \alpha_2 = 2(1 - R)U^2 = \eta_{tt} \left(\Delta h_{is} - \frac{1}{2}c_x^2 \right) \quad (\text{A.2})$$

after some rearranging.

Using $\phi = c_x/U$ in the preceding and with a little more rearranging we get:

$$U^2 = \frac{\eta_{tt} \Delta h_{is}}{2(1 - R) + \frac{1}{2}\eta_{tt}\phi^2}. \quad (\text{A.3})$$

Using the values of the parameters given in the design requirements, we get

$$U = 315.6 \text{ m/s and } c_x = 126.3 \text{ m/s.}$$

From eqn. (A.2), $\Delta W = 2(1 - R)U^2 = 119.6 \text{ kJ/kg}$,

$$\begin{aligned} \tan \alpha_2 &= \frac{\Delta W}{U c_x} = \frac{119.55 \times 10^3}{315.6 \times 126.3} = 3.0, \\ \alpha_2 &= 71.56^\circ. \end{aligned}$$

DETERMINING THE MEAN RADIUS VELOCITY TRIANGLES AND EFFICIENCY

We can easily determine the rest of the data necessary to calculate the total-to-total efficiency. For $\alpha_3 = 0^\circ$,

$$\tan \beta_3 = U/c_x = 1/\phi = 2.5, \text{ so } \beta_3 = 68.2^\circ.$$

From eqn. (4.13b) with $\alpha_3 = 0^\circ$,

$$\tan \beta_2 = \tan \beta_3 - 2R/\phi = 0.5, \text{ so } \beta_2 = 26.57^\circ,$$

$$w_3 = c_x/\cos \beta_3 = 340.1 \text{ m/s,}$$

$$c_2 = c_x/\cos \alpha_2 = 399.3 \text{ m/s.}$$

From eqn. (4.20b), we use the approximation for the total-to-total efficiency recommended for initial calculations, i.e.,

$$\eta_{tt} = \left[1 + \frac{\zeta_R w_3^2 + \zeta_N c_2^2}{2\Delta W} \right]^{-1}.$$

The Soderberg loss coefficients, in their simplest form, are used,

$$\zeta = 0.04[1 + 1.5(\varepsilon/100)^2].$$

For the rotor, $\varepsilon_R = \beta_2 + \beta_3 = 94.77^\circ$, hence, $\zeta = 0.0939$.

For the nozzle row, $\varepsilon_N = \alpha_2 = 71.56^\circ$, hence, $\zeta = 0.0707$.

Evaluating the total-to-total efficiency using these data, $\eta_{tt} = 91.5\%$.

This is fairly close to the value originally used in the calculations and a further iteration at this stage of the design with this new value is not really necessary.

The total-to-static efficiency can be evaluated from eqn. (4.21b), i.e.,

$$\eta_{ts} = \left[1 + \frac{\zeta_R w_3^2 + \zeta_N c_2^2 + c_x^2}{2\Delta W} \right]^{-1}.$$

Hence, we get, $\eta_{ts} = 86.26\%$.

It is worth noting that values of total-to-static efficiency are shown in Figure 4.17 for a stage with axial flow at exit with the coordinate axes, stage loading coefficient, $\psi = \Delta W/U^2$, and flow coefficient, $\phi = c_x/U$. In the present design the value of $\psi = 1.2$ and $R = 0.4$ at the mean radius and, not unexpectedly, we obtain complete accord for the value of η_{ts} from the graph.

The nozzle exit Mach number $M_2 = c_2/\sqrt{\gamma RT_2}$ is now determined:

$$T_2 = T_{01} - c_2^2/(2C_p) = 705.3 \text{ K},$$

$$\gamma R = (\gamma - 1)C_p,$$

$$M_2 = 0.774.$$

Note: Turbine stages can be designed to operate at much higher loads, i.e., with larger available pressure ratios, resulting in supersonic absolute flow at nozzle exit and possibly supersonic relative flow into the rotor. For such flows shock wave systems will occur and some loss in efficiency is then inevitable. Supersonic and transonic flows in axial turbine cascades are discussed in Chapters 3.

DETERMINING THE ROOT AND TIP RADII

The axial flow area at nozzle exit is $A_2 = \dot{m}/(\rho_2 c_x)$ where $\rho_2 = p_2/(RT_2)$. We need to determine the static pressure p_2 taking into account the nozzle losses. It is easily shown that

$$\frac{p_2}{p_{01}} = \left(\frac{T_{2s}}{T_{01}} \right)^{\gamma/(\gamma-1)}$$

Table A.1

r_h/r_t	0.75	0.8	0.85	0.9	Notes
r_t /(cm)	25.56	28.17	32.09	38.78	
H /(cm)	6.39	5.634	4.814	3.878	Blade height
U_t /(m/s)	360.7	350.7	341.2	332.2	Tip speed
$\frac{\sigma_c/\rho_m}{10^4 \text{m}^2/\text{s}^2}$	2.846	2.214	1.615	1.048	
σ_c /(MPa)	223.4	173.8	126.8	104.8	Centrifugal stress
N /(rev/min)	13,476	11,887	10,153	8,180	Rotor speed
R_h	0.18	0.24	0.29	0.33	Reaction at the hub
Z	44	56.5	77.5	119	No. blades with $H/s = 2$

and, for a nozzle,

$$\left(1 - \frac{T_{2s}}{T_{01}}\right) = \left(1 - \frac{T_2}{T_{01}}\right) / \eta_N.$$

At this point in the design we have no information on the magnitude of nozzle efficiency. However, in a nozzle the losses will be low and a value $\eta_N = 0.97$ is selected. Using this value and earlier data, determine $T_{2s}/T_{01} = 0.9097$. Hence,

$$p_2 = 0.6768p_{01} = 1.4213 \times 10^5 \text{ Pa as } p_{01} = 2.1 \times 10^5 \text{ Pa.}$$

Thus, $\rho_2 = p_2/(RT_2) = 0.7056 \text{ kg/m}^3$ with $R = 285.6 \text{ kJ/kg}^\circ\text{C}$. Therefore, the flow area

$$A_2 = \frac{\dot{m}}{\rho_2 c_x} = \frac{8}{0.7056 \times 126.3} = 0.08977 \text{ m}^2.$$

In Table A.1 several values of hub–tip ratio have been selected to discover the most suitable blade aspect ratio, rotational speed, and blade root stress for the turbine rotor. Equation (4.34a) gives the centrifugal stress developed at the root of the rotor blades. It is assumed that the blades are untapered and made of steel ($\rho_m = 7850 \text{ kg/m}^3$).

The blade tip radius is determined from eqn. (4.25),

$$r_t = \sqrt{A_2/\pi[1 - (r_h/r_t)^2]}$$

and the average blade temperature $T_b = 721 \text{ K}$ is determined from eqn. (4.35).

Comparing the stress divided by density values with the rather limited data given in Figure 4.20, the stress levels are quite low and there appears to be no limitation in using untapered steel blades.

VARIATION OF REACTION AT THE HUB

In Chapter 6 an application of free-vortex flow was made to an axial flow compressor where it was shown that the reaction increases radially as we go from root to tip, see eqn. (6.9). The same result applies to the axial-flow turbine stage and here our interest must be directed to how small the reaction becomes at the hub. This is important as losses can become large when the reaction is very low or even negative.

Table A.2 Data for the Calculated Velocity Triangles

r/r_t	α_2 (deg)	β_2 (deg)	β_3 (deg)	U (m/s)	R_h
1.0	69.14	-13.0	70.7	360.7	0.54
0.875	71.6	26.6	68.2	315.6	0.4
0.75	74.1	53.7	65.0	270.5	0.183

Note: Axial velocity $c_x = 126.3$ m/s at all radii.

From eqn. (A.1), for all radii,

$$R = 1 - \frac{c_x \tan \alpha_2}{2U} = 1 - \frac{c_{\theta 2}}{2U} = 1 - \frac{K}{2Ur}.$$

When referring to particular flow conditions at the mean radius the subscript m will be added to the variables R and r . Thus,

$$R_m = 1 - \frac{K}{2U_m r_m}.$$

Combining these expressions the radial variation of reaction is

$$R = 1 - (1 - R_m) \left(\frac{r_m}{r} \right)^2.$$

Values of R at the hub radius r_h are given in Table A.2 as a function of r_h/r_t . The value of r_h/r_t at which $R = 0$ is 0.632.

CHOOSING A SUITABLE STAGE GEOMETRY

Deciding on a suitable configuration for the turbine is not so easy as several factors need to be considered in making a decision. The size of the unit can be of importance and usually the turbocharger needs to be made as small as possible. As shown in Table A.1, by making r_t smaller the speed of rotation must increase. As a result both the blade length and the root stress are increased. It is also necessary to check that the blade pitch s is not so small that the blades cannot be safely attached to the rim of the turbine disc. In small turbines such as this design it may be practicable to consider either machining the blades and disc from a single forging or welding the blades onto the disc.

The blade aspect ratio H/s is another factor that can affect the efficient working of the turbine. This ratio needs to be sufficiently large that the end wall losses and secondary flow losses do not become excessive. A just acceptable value of H/s is 2.0 and, in Table A.1, the values of $Z = 2\pi r_m/s$ resulting from this choice are shown.

Although the decision is not absolutely clear cut, on balance the present designer favours the smallest size of the selection, $r_h/r_t = 0.75$ with 44 blades. With the sizing choice having now been made the flow angles at the root and tip radii are determined and the velocity diagrams are added to Figure A.2.

FIGURE A.2

Velocity Triangles for Root, Mean, and Tip Radii

For the nozzle blades, as a precaution against the possibility of inducing resonant frequencies between the rotor blades and the nozzle blades the number of nozzle blades is chosen to be 45, thereby avoiding common multiples.

ESTIMATING THE PITCH/CHORD RATIO

Referring to the measured profile loss coefficients for turbine nozzle and impulse blades, the data of Figure 3.24, indicate two significant trends:

- (i) losses increase generally as the flow deflection increases;
- (ii) the greater the flow deflection required, the lower must be the pitch–chord ratio to minimise the losses.

The simplified form of Zweifel’s criterion, eqn. (3.55) can be applied to the mean radius of the rotor:

$$Z = 2(s/b)\cos^2\beta_3(\tan\beta_3 + \tan\beta_2) = 0.8,$$

with $\beta_2 = 26.6^\circ$ and $\beta_3 = 68.2^\circ$ we get

$$s/b = 0.8/0.8275 = 0.967.$$

The relationship between the axial chord, b , and the true chord, l , of a blade row is not simple or at all obvious. However, a simple, approximate geometric relationship can be found based upon the assumption of a single circular arc to represent the camber line of a turbine blade in a cascade,

FIGURE A.3

Construction Details to Determine Stagger Angle

as shown in Figure A.3. From the construction details shown in this figure the stagger angle ξ can be obtained from

$$\tan \xi = \frac{\cos \beta_2' - \cos \beta_3'}{\sin \beta_2' + \sin \beta_3'}.$$

Making a crude approximation we can substitute the relative flow angles β_2 and β_3 into this expression and so deriving a “stagger” angle,

$$\begin{aligned} \tan \xi &= \frac{\cos 26.6 - \cos 68.2}{\sin 26.6 + \sin 68.2} = \frac{0.5228}{1.376} = 0.3798 \\ \xi &= 20.8^\circ. \end{aligned}$$

Hence, $s/l = (s/b)(b/l) = 0.967 \times \cos 20.8 = 0.903$.

This space-chord ratio appears to be suitable and is in agreement with the values found by Ainley and Mathieson (1951), Figure 3.24, although the exact value is not crucial.

The velocity triangles for the root, mean, and tip radii are drawn in Figure A.2. Equation (4.15) can be used to obtain the relative flow angles shown in Table A.2 with $\alpha_3 = 0$.

BLADE ANGLES AND GAS FLOW ANGLES

A point well worth remembering is that the velocity triangles relate to the gas angles and not to the blade angles. Cascade results for impulse and reaction blades, e.g., Figure 3.25, show that the profile loss coefficients for reaction blades are not very sensitive to the angle of incidence over a wide range (-20° to 15°). This means that in the preliminary design exercise the rotor blades can have less twist along their length, i.e., blade sections may operate at varying amounts of incidence without incurring excessive losses.

Table A.3

Radius, cm	$r_h = 19.17$ cm	$r_m = 22.37$ cm	$r_t = 25.56$ cm
Nozzle exit Mach number	0.906	0.74	0.682
Nozzle exit velocity/(m/s)	460	399	355

ADDITIONAL INFORMATION CONCERNING THE DESIGN

Power output,	$\dot{m}\Delta W = 956.4$ kW;
Rotational speed,	$N = 13,476$ rev/min;
Rotor tip radius,	$r_t = 25.56$ cm;
Rotor blade chord	$l = 4.56$ cm;
Rotor blade temperature,	$T_b = 772$ K.

See also Table A.3.

POSTSCRIPT

The initial design described is one of many possible methods that could be employed and was governed by the initial assumptions (free-vortex design, choices of degree of reaction, and flow coefficient) as well as decisions made about the radius ratio and blading. Students could further investigate the effect of increasing the value of the flow coefficient (so reducing the turbine diameter), increasing the reaction ratio or using a non-free-vortex flow such as the *first power stage design*, eqn. (6.15). In all such design attempts it would be wise to check the values of reaction and Mach number at the blade root for reasons given earlier.

Appendix B: Preliminary Design of a Centrifugal Compressor for a Turbocharger

This design is a follow-up to the preliminary turbine design given in Appendix A to which it is linked. The power delivered to the compressor will be rather less than that produced by the turbine to allow for bearing frictional losses. The air mass flow entering the compressor will be lower than the products of combustion entering the turbine because of the fuel used by the engine. The rotational speed of the compressor is the same as that of the turbine as they are on the same shaft.

For the turbine, a premium was placed on small size, so that for the compressor a vaned diffuser will be needed to restrict the size of the turbocompressor. Pre-whirl of the inlet flow will not be required both to simplify the design and because of the expected fairly low Mach numbers. As this compressor is not a heavily loaded, high performance design, the use of backward swept impeller vanes is unlikely to confer much advantage in comparison with a design having radial vanes. In fact, certain attributes associated with backward swept vanes suggest that a higher overall efficiency can be achieved although this design study has not been extended to include such vanes.

DESIGN REQUIREMENTS AND ASSUMPTIONS

Power supplied by the turbine (allowing for bearing friction), P ,	947 kW;
Rotational speed, N ,	13,476 rev/min;
Air mass flow, \dot{m} ,	7.5 kg/s;
Inlet stagnation temperature, T_{01} ,	293 K;
Inlet stagnation pressure, p_{01} ,	105 kPa;
Assume a constant value of specific heat, C_p ,	1.005 kJ/kg°C;
Assume a constant value of ratio of specific heats, γ ,	1.4;
The number of rotor blades is, Z ,	21.

DETERMINING THE BLADE SPEED AND IMPELLER RADIUS

The specific work is $\Delta W = P/\dot{m} = 947 \times 10^3 / 7.5 = \mathbf{126.3 \times 10^3 \text{ m}^2/\text{s}^2}$.¹

The impeller radius is easily found since $\Delta W = U_2 c_{\theta 2}$ and, using the Stanitz expression for the slip factor, $\sigma = 0.63 \pi/Z = c_{\theta 2}/U_2 = \mathbf{0.9057}$:

$$U_2 = \sqrt{\Delta W / \sigma} = \mathbf{373.4 \text{ m/s}},$$

$$r_2 = U_2 / \Omega = \mathbf{0.265 \text{ m}} \text{ as } \Omega = \mathbf{1411 \text{ rad/s}}.$$

¹Results shown in **bold** will be referred to later.

DESIGN OF IMPELLER INLET

Several alternative methods can be used to start the design of the inlet. We can choose a particular ratio of r_{s1}/r_2 , usually in the range 0.35 to 0.65, and select an axial velocity to blade tip speed ratio at inlet, c_{x1}/U_{s1} , in the range 0.4 to 0.5, then proceed from there to calculate the hub–tip radius ratio from the continuity equation. The magnitude of the maximum relative Mach number at the inlet, $M_{1,rel}$, at the shroud radius r_{s1} can then be checked and further repeat adjustments made as required to the values of r_{h1}/r_2 and c_{x1}/U_{s1} .

A more direct method is available using the theory already developed leading to eqn. (7.24a). The inlet radius ratio can be determined by a suitable choice of the *relative* inlet Mach number $M_{1,rel}$ at the shroud. Referring to eqn. (7.23a) with $\gamma = 1.4$, this is

$$f(M_{1,rel}) = \frac{\Omega^2 \dot{m}}{\pi k p_{01} \gamma a_{01}} = \frac{M_{1,rel}^3 \sin^2 \beta_{s1} \cos \beta_{s1}}{\left(1 + \frac{1}{5} M_{1,rel}^2 \cos^2 \beta_{s1}\right)^4}, \quad (7.24a)$$

where $k = 1 - (r_{h1}/r_{s1})^2$. For $\alpha_1 = 0$ and a fixed value of $M_{1,rel}$, the optimum value of β_{s1} , is at the maximum value of $f(M_{1,rel})$ (see Figure 7.11). For a fixed value of $M_{1,rel}$, it can be shown by differentiating the right-hand side of eqn. (7.24a), that this maximum occurs when

$$\cos^2 \beta_{s1} = X - \sqrt{X^2 - 1/M_{1,rel}^2},$$

where $X = 0.7 + 1.5/M_{1,rel}^2$.

Using the given or derived data, several optimum values of k and hub–tip ratios have been determined (to illustrate the trend) for a range of values of $M_{1,rel}$, shown in Table B.1.

The value $r_{h1}/r_{s1} = 0.443$ is in the normal range used in practice and corresponds to $M_{1,rel} = 0.7$, which seems satisfactory.

The inlet dimensions are now easily found with the equation of continuity, $\dot{m} = \rho_1 A_1 c_{x1}$:

$$r_{s1}^2 = \frac{\dot{m}}{\pi k \rho_1 c_{x1}},$$

where $\rho_1 = \rho_{01} / \left[1 + \frac{1}{5} M_1^2\right]^{2.5}$ and $c_{x1} = M_1 a_1$,

$$M_1 = M_{1,rel} \cos \beta_{s1} = 0.7 \times \cos 57.94 = \mathbf{0.3716},$$

$$a_1 = a_{01} / \left[1 + \frac{1}{5} M_1^2\right]^{0.5} = 338.5 \text{ m/s},$$

Table B.1

$M_{1,rel}$	0.7	0.75	0.8	0.85
Max of right-hand side of eqn. (7.24a)	0.1173	0.1420	0.1695	0.2000
β_{s1} (deg) at max of $f(M_{1,rel})$	57.94	58.36	58.78	59.25
k	0.8037	0.6640	0.5560	0.4715
r_{h1}/r_{s1}	0.4430	0.5796	0.666	0.7270

and

$$c_{x1} = 0.3716 \times 338.5 = 125.8 \text{ m/s.}$$

As $\rho_{01} = p_{01}/(RT_{01}) = 1.249 \text{ kg/m}^3$, $\rho_1 = 1.249/1.0704 = 1.1669 \text{ kg/m}^3$. Thus, $r_{s1}^2 = 7.5/(\pi \times 0.8037 \times 1.1669 \times 125.8) = 0.02024$ and

$$r_{s1} = \mathbf{0.1423 \text{ m}} \text{ and } r_{h1} = \mathbf{0.0630 \text{ m.}}$$

EFFICIENCY CONSIDERATIONS FOR THE IMPELLER

In well-designed radial-vaned impellers the stagnation pressure losses are not large and isentropic efficiencies up to 92% have been attained at the optimum specific speed, $N_s \approx 0.6$ to 0.7 .² The reason for the high efficiency achieved by centrifugal compressor impellers is because of the major contribution made to the compression process by the *frictionless* centrifugal term $\frac{1}{2}(U_2^2 - U_1^2)$, shown in eqn. (7.2). Rodgers (1980) noted that impellers with between 25° and 50° of backsweep were found to give around 2% higher efficiency than those with radial vanes. Notwithstanding the efficiency advantage of backswept vanes we shall persist with radial vanes because of their greater simplicity and obviously lower manufacturing cost. In the present radially bladed impeller it seems quite reasonable to assume an isentropic efficiency $\eta_i = 92\%$ for the impeller, and this value is used in the following calculations.

DESIGN OF IMPELLER EXIT

Designers often choose a value for the radial component of velocity c_{r2} at impeller exit equal to the axial velocity c_{x1} at impeller entry. Hence, we shall use $c_{r2} = \mathbf{125.8 \text{ m/s}}$.

As $U_2 = 373.4 \text{ m/s}$ and $\sigma = 0.9057$ then $c_{\theta 2} = \mathbf{338.2 \text{ m/s}}$,

$$c_2 = \sqrt{c_{\theta 2}^2 + c_{r2}^2} = \mathbf{360.8 \text{ m/s}}$$

and the flow angle $\alpha_2 = \tan^{-1}(c_{\theta 2}/c_{r2}) = \mathbf{69.60^\circ}$ (measured from the radial direction).

From the continuity equation, eqn. (1.8), $\dot{m} = \rho_2 A_2 c_{r2} = 7.5 \text{ kg/s}$ and $A_2 = 2\pi r_2 b_2$, so to solve for b_2 we need to determine the density, $\rho_2 = p_2/(RT_2)$.

Now

$$\eta_i = \frac{h_{02s} - h_{01}}{h_{02} - h_{01}} = \frac{T_{02s}/T_{01} - 1}{T_{02}/T_{01} - 1}$$

and

$$\frac{T_{02}}{T_{01}} = \frac{\Delta W}{C_p T_{01}} + 1 = \mathbf{1.4289}$$

and $T_{02} = \mathbf{418.7 \text{ K}}$.

²In this design $N_s = \phi^{0.5}/\psi^{0.75}$, where $\phi = c_{x1}/U_2 = 118.7/373.4 = 0.3179$ and $\psi = \Delta W/U_2^2 = 126.3 \times 10^3/373.4^2 = 0.9058$. Hence, $N_s = 0.607$ (based on inlet axial velocity).

Hence, with $\eta_i = 0.92$, we obtain $T_{02s}/T_{01} = \mathbf{1.3946}$ and $p_{02}/p_{01} = \mathbf{3.203}$; therefore,

$$p_{02} = \mathbf{336.3 \text{ kPa}},$$

$$T_2 = T_{02} - \frac{c_2^2}{2C_p} = \mathbf{353.9 \text{ K}} \text{ so } T_2/T_{01} = \mathbf{1.2080} \text{ and } T_{02}/T_2 = \mathbf{1.1830},$$

$$p_2 = p_{02} \left/ \left(\frac{T_{02}}{T_2} \right)^{\gamma/(\gamma-1)} \right. = \mathbf{186.7 \text{ kPa}}.$$

Hence, $\rho_2 = p_2/RT_2 = 186.7 \times 10^3 / (287 \times 353.9) = 1.838 \text{ kg/m}^3$, so

$$b_2 = \dot{m} / (2\pi\rho_2 c_{r2} r_2) = 0.0195 \text{ m} = \mathbf{1.95 \text{ cm}},$$

$$\frac{b_2}{r_2} = \frac{1.95}{26.5} = 0.0736.$$

At impeller exit the Mach number, $M_2 = c_2/a_2$, where $a_2 = \sqrt{\gamma RT_2} = 377.1 \text{ m/s}$,

$$M_2 = 360.8/377.1 = \mathbf{0.957}.$$

FLOW IN THE VANELESS SPACE

The region between the impeller exit, radius r_2 and the start of the diffuser vanes at radius r_{2d} is known as the *vaneless space* and within this space the flow is treated as though it was in a vaneless diffuser (see notes on Vaneless diffusers). The flow leaving the impeller is known to have extensive regions of separated flow and to be highly non-uniform and may have strong, deleterious effects on the diffuser performance. Having a vaneless space allows some flow diffusion to take place but also allows some reduction of these flow irregularities before entry into the diffuser vanes.

The minimum radius ratio for the vaneless space, r_{2d}/r_2 , mentioned by Cumpsty (1989) and others is 1.1, although this ratio could be further increased if necessary to reduce the Mach number of the flow at entry to the vanes. In the case of the present design the Mach number, M_2 , is not excessive so that this measure is not needed. We will assume that the axial width of the vaneless space remains constant at $b_2 = \mathbf{1.95 \text{ cm}}$.

Despite the known highly irregular flow entering the vaneless space it is usually assumed for the purposes of a preliminary design that a smoothed out and frictionless flow exists. It is assumed for simplicity that the flow is frictionless, that the tangential momentum is conserved within the vaneless space. In Chapter 7 the flow in a parallel walled diffuser was assumed to be incompressible and this led to the idea of a *logarithmic spiral* flow path as described by eqn. (7.53).

We may determine the tangential velocity at the radius $r_{2d} = 1.1r_2$ from

$$\frac{c_{\theta 2d}}{c_{\theta 2}} = \frac{r_2}{r_{2d}} \text{ so } c_{\theta 2d} = 338.2/1.1 = \mathbf{307.5 \text{ m/s}},$$

$$c_{r2d} = \frac{r_2}{r_{2d}} c_{r2} = 114.36 \text{ m/s}, \alpha_{2d} = \cos^{-1}(114.36/307.5) = \mathbf{68.16^\circ},$$

$$c_{2d} = (c_{2d}^2 + c_{r2d}^2)^{0.5} = 328.1 \text{ m/s}, \quad T_{2d} = T_{02} - c_{2d}^2 / (2C_p) = 418.7 - 328.1^2 / 2010 = 365.2 \text{ K},$$

$$a_{2d} = (\gamma RT_{2d})^{0.5} = 383.0, \text{ so } M_{2d} = 328.1 / 383 = \mathbf{0.856}.$$

An Iterative Procedure

The flow at entry to our vaneless diffuser space is in a high subsonic Mach number range and one might expect a significant change in Mach number to occur across the diffuser. So, in the following analysis a progressive series of approximations is used to try and discover just how much the density (and Mach number) changes.

In the *first approximation*, the radial velocity at radius r_{2d} is obtained using the incompressible log-spiral approximation:

$$c_{r2d} = c_{r2}(r_2/r_{2d}) = 125.8/1.1 = 114.3.$$

Hence,

$$c_{2d} = (c_{\theta 2d}^2 + c_{r2d}^2)^{0.5} = (307.5^2 + 114.3^2)^{0.5} = 328.06 \text{ m/s}.$$

In the *second approximation*, we can determine T_{2d} and p_{2d} at radius r_{2d} :

$$T_{2d} = T_{02} - c_{2d}^2 / 2C_p = 418.7 - 328.062 / 2010 = 365.2 \text{ K},$$

$$p_{2d} = p_{02} / (T_{02}/T_{2d})^{\gamma/(\gamma-1)} = 336.3 \times 10^3 / (418.7/365.2)^{3.5} = 208.4 \text{ kPa},$$

$$\rho_{2d} = \frac{p_{2d}}{RT_{2d}} = \frac{208.4 \times 10^3}{287 \times 365.2} = 1.988 \text{ kg/m}^3,$$

$$A_{2d} = 2\pi r_{2d} b_2 = 2\pi \times 0.2915 \times 0.0195 = 0.03572 \text{ m}^2,$$

so that

$$c_{r2} = \dot{m} / (\rho_{2d} A_{2d}) = 7.5 / (1.988 \times 0.03572) = 105.6 \text{ m/s},$$

$$c_{2d} = (105.6^2 + 307.5^2)^{0.5} = 325.1 \text{ m/s}.$$

For the third approximation,

$$T_{2d} = T_{02d} - c_{2d}^2 / (2C_p) = 418.7 - 325.1^2 / 2010 = 366.1 \text{ K},$$

$$P_{2d} = P_{02d} / (T_{02d}/T_{2d})^{\gamma/(\gamma-1)} = 336.3 / (418.7/366.1)^{3.5} = 210.2 \text{ kPa},$$

$$\rho_{2d} = 210.2 / (287 \times 366.1) = 2.000 \text{ kg/m}^3,$$

$$c_{r2d} = \dot{m} / (\rho_{2d} A_{2d}) = 7.5 / (2.00 \times 0.03572) = 104.98 \text{ m/s},$$

therefore,

$$c_{2d} = (104.98^2 + 307.5^2)^{0.5} = 324.9 \text{ m/s}.$$

This iteration has provided sufficient convergence so that the Mach number M_{2d} and flow angle α_{2d} can be determined:

$$M_{2d} = c_{2d} / \sqrt{\gamma R T_{2d}} = 324.9 / \sqrt{1.4 \times 287 \times 366.1} = \mathbf{0.847},$$

$$\alpha_{2d} = \tan^{-1}(c_{\theta 2d} / c_{r 2d}) = \tan^{-1}(307.5 / 104.98) = \mathbf{71.15^\circ}.$$

This calculation shows that, for this spiraling flow with a high subsonic Mach number, the change in radius between the impeller exit and the entrance to the vaned diffuser actually causes only a small change in Mach number and flow angle.

A more elegant method of solution for the flow in the vaneless space is to use the compressible flow equation:

$$\frac{\dot{m}}{A_n p_0} \sqrt{C_p T_0} = \frac{\gamma M}{\sqrt{\gamma - 1}} \left(1 + \frac{\gamma - 1}{2} M^2 \right)^{\frac{1}{2}[(\gamma + 1)/(\gamma - 1)]}. \quad (1.38)$$

In the vaneless space the values of \dot{m} , C_p , T_0 , and p_0 are constant by assumption and $\gamma = 1.4$. Thus, the equation reduces to

$$\frac{A_n M}{\left(1 + \frac{1}{5} M^2\right)^3} = \text{constant}.$$

It will be appreciated that A_n is the area $2\pi r b$ and the change in area we are considering is controlled by the radial direction r . It is thus necessary to apply this expression to the change in radius from r_2 to r_{2d} using the radial component of M .

At entry to the vaneless space, $M_2 = 0.957$ and $\alpha_2 = 69.6^\circ$, so that $M_{2r} = 0.957 \cos 69.6^\circ = 0.3336$. Hence, we need to solve for M_{2r} in the expression

$$\frac{r_2 M_{2r}}{\left(1 + \frac{1}{5} M_{2r}^2\right)^3} = \frac{r_{2d} M_{2dr}}{\left(1 + \frac{1}{5} M_{2dr}^2\right)^3}.$$

Substituting $r_{2d}/r_2 = 1.1$ and $M_{2r} = 0.3336$ we can solve iteratively (or using tables) to obtain $M_{2r} = 0.2995$. With $\alpha_2 = 69.6^\circ$, we find $M_{2d} = \mathbf{0.858}$.

Determining the Mach number change across the vaneless space may be regarded (in this instance) as just an exercise in the use of the compressible flow equation. The result obtained varies only slightly from that determined using incompressible flow analysis.

THE VANED DIFFUSER

From Figure 7.9 (with $L/W_1 = 8$) a good choice of a plate diffuser would be one with $2\theta = 8^\circ$, corresponding, at this point, to the values $C_p = 0.7$ and $C_{p, id} = 0.8$. This is close to the maximum efficiency condition for this type of diffuser and, according to the data shown in Figure 7.8, is in the flow regime that avoids stall.

From eqn. (7.10) the static pressure at diffuser exit will be

$$p_3 = p_{2d} + C_p q_{2d} = 210.2 + 0.7 \times 105.6 = 284.1 \text{ kPa},$$

and by using eqn. (7.13) the exit velocity will be

$$c_3 = c_{2d}(1 - C_{p,id})^{0.5} = 324.9(1 - 0.8)^{0.5} = \mathbf{145.3 \text{ m/s}}.$$

The actual number of diffuser “nozzles” is fairly arbitrary but is usually chosen to be much less than the number of impeller vanes. In this design the number chosen is $Z = 12$ corresponding with common practice in manufacturing.

THE VOLUTE

The purpose of the volute (or scroll), shown in Figure 7.4, is simply to collect the compressed air leaving the diffuser and guide it to the engine air intake. The energy losses in the volute are partly the result of the dissipation of the kinetic energy at diffuser exit due to turbulent mixing and partly due to friction on the solid surfaces of the volute. According to Watson and Janota (1982) the total loss in the volute is usually assumed to be (about) half of the dynamic pressure leaving the diffuser. Here, we shall assume this extra loss is exactly half of the available dynamic pressure.

DETERMINING THE EXIT STAGNATION PRESSURE, p_{03} , AND OVERALL EFFICIENCY, η_c

We determine the density, $\rho_3 = p_3/RT_3$, where $T_3 = T_{03} - c_3^2/(2C_p) = 411.9 \text{ K}$ and $p_3 = 284.1 \text{ kPa}$. Hence, $\rho_3 = 2.409 \text{ kg/m}^3$.

Immediately on leaving the diffuser the total pressure is approximately $p_{03} = p_3 + q_3$ where $q_3 = \frac{1}{2}\rho_3 c_3^2$, and $q_3 = 16.4 \text{ kPa}$, hence, $p_{03} = 300.9 \text{ kPa}$. Because of the total pressure losses in the volute mentioned previously the final total pressure at compressor exit is estimated as $p_{03} = p_3 + \frac{1}{2}q_3 = \mathbf{293 \text{ kPa}}$.

The overall compressor efficiency η_c can be found with eqn. (7.21):

$$\eta_c = C_p T_{01} (T_{03ss}/T_{01} - 1) / \Delta W,$$

where $T_{03ss}/T_{01} = (p_{03}/p_{01})^{\frac{1}{\gamma}} = 1.3407$. Thus,

$$\eta_c = 0.794.$$

This value of overall efficiency is rather low and can be attributed to the poor diffuser efficiency ($\eta_D = 0.805$). The performance of the conical diffuser is known to be fairly resistant to stall, particularly with the flow issuing from the impeller, which is turbulent and unsteady. So, another attempt is made to redesign the diffuser with $C_p = C_p^* = 0.8$.

Again, from Figure 7.26 the new values of $A_2/A_1 = 4.42$ and $N/R_1 = 18.8$:

$$C_{p,id}^* = 1 - 1/A_R^2 = 0.9490 \text{ and } \eta_D = C_p^*/C_{p,id}^* = \mathbf{0.843}.$$

Following the previous calculations the results obtained for the new diffuser are

$$\begin{aligned}p_3 &= 295.3 \text{ kPa;} \\c_3 &= 73.0 \text{ m/s;} \\T_3 &= 416.0 \text{ K;} \\ \rho_3 &= 2.473 \text{ kg/m}^3;\end{aligned}$$

and

$$p_{03} = 301.9 \text{ kPa.}$$

With the volute loss included, $p_{03'} = 298.6 \text{ kPa}$.

Thus, $T_{03ss}/T_{01} = (298.6/105)^{\frac{1}{3.5}} - 1.3480$ and the compressor efficiency is

$$\eta_c = 81.1\%.$$

This is a substantial improvement on the previous value. The student will have realized that the subject of design provides a seemingly infinite number of choices and the best one can do is to use any well-founded guidance that is available. On this topic it was remarked by Cumpsty (1989) that the procedures used by most organizations involved in the design of compressors are shrouded in commercial secrecy. New designs are somehow evolved often based upon older successful designs and as long as the new product gives satisfactory test results then some sort progress can be claimed.

Appendix C: Tables for the Compressible Flow of a Perfect Gas

The tables in this appendix are required for some of the problems in the book. All results are quoted to four decimal places at equal intervals of Mach number so that linear interpolation can be easily applied where required. In most cases this will give adequate accuracy, but if necessary improved precision can be obtained by direct application of the formulae that follow:

Static and Stagnation Quantities	Flow Relations
$\frac{T}{T_0} = \left(1 + \frac{\gamma-1}{2} M^2\right)^{-1}$	$c = M\sqrt{\gamma RT}, \frac{c}{\sqrt{C_p T_0}} = M\sqrt{\gamma-1} \left(1 + \frac{\gamma-1}{2} M^2\right)^{-\frac{1}{2}}$
$\frac{p}{p_0} = \left(1 + \frac{\gamma-1}{2} M^2\right)^{-\gamma/(\gamma-1)}$	$\dot{m} = \rho c A_n, \frac{\dot{m}\sqrt{C_p T_0}}{A_n p_0} = \frac{\gamma}{\sqrt{\gamma-1}} M \left(1 + \frac{\gamma-1}{2} M^2\right)^{-\frac{1}{2}[(\gamma+1)/(\gamma-1)]}$
$\frac{\rho}{\rho_0} = \left(1 + \frac{\gamma-1}{2} M^2\right)^{-1/(\gamma-1)}$	

Note that in steady, adiabatic flow with no shaft work, T_0 is constant. If the flow is also isentropic, p_0 and ρ_0 are also constant.

Through a steady flow turbomachinery device, the mass flow rate will be conserved such that \dot{m} is constant.

Table C.1 shows results for $\gamma = 1.4$ (applicable to dry air and diatomic gases). Table C.2 shows results for $\gamma = 1.333$ (typical of gas turbine combustion products).

Table C.1 Compressible Flow for a Perfect Gas, $\gamma = 1.4$

Appendix D: Conversion of British and American Units to SI Units

Length

$$1 \text{ inch} = 0.0254 \text{ m}$$

$$1 \text{ foot} = 0.3048 \text{ m}$$

Area

$$1 \text{ in}^2 = 6.452 \times 10^{-4} \text{ m}^2$$

$$1 \text{ ft}^2 = 0.09290 \text{ m}^2$$

Volume

$$1 \text{ in}^3 = 16.39 \text{ cm}^3$$

$$1 \text{ ft}^3 = 28.32 \text{ dm}^3 \\ = 0.02832 \text{ m}^3$$

$$1 \text{ gall (UK)} = 4.546 \text{ dm}^3$$

$$1 \text{ gall (US)} = 3.785 \text{ dm}^3$$

Velocity

$$1 \text{ ft/s} = 0.3048 \text{ m/s}$$

$$1 \text{ mile/h} = 0.447 \text{ m/s}$$

Mass

$$1 \text{ lb} = 0.4536 \text{ kg}$$

$$1 \text{ ton (UK)} = 1016 \text{ kg}$$

Density

$$1 \text{ lb/ft}^3 = 16.02 \text{ kg/m}^3$$

$$1 \text{ slug/ft}^3 = 515.4 \text{ kg/m}^3$$

Force

$$1 \text{ lbf} = 4.448 \text{ N}$$

$$1 \text{ ton f (UK)} = 9.964 \text{ kN}$$

Pressure

$$1 \text{ lbf/in}^2 = 6.895 \text{ kPa}$$

$$1 \text{ ft H}_2\text{O} = 2.989 \text{ kPa}$$

$$1 \text{ in Hg} = 3.386 \text{ kPa}$$

$$1 \text{ bar} = 100.0 \text{ kPa}$$

Energy

$$1 \text{ ft lbf} = 1.356 \text{ J}$$

$$1 \text{ Btu} = 1.055 \text{ kJ}$$

Specific energy

$$1 \text{ ft lbf/lb} = 2.989 \text{ J/kg}$$

$$1 \text{ Btu/lb} = 2.326 \text{ kJ/kg}$$

Specific heat capacity

$$1 \text{ ft lbf/(lb}^\circ\text{F)} = 5.38 \text{ J/(kg}^\circ\text{C)}$$

$$1 \text{ ft lbf/(slug}^\circ\text{F)} = 0.167 \text{ J/(kg}^\circ\text{C)}$$

$$1 \text{ Btu/(lb}^\circ\text{F)} = 4.188 \text{ kJ/(kg}^\circ\text{C)}$$

Power

$$1 \text{ hp} = 0.7457 \text{ kW}$$

Appendix E: Answers to Problems

CHAPTER 1

1. 88.1%.
 2. (i) 704 K; (ii) 750 K; (iii) 668 K.
 3. (i) 500 K, 0.313 m³/kg; (ii) 1.042.
 4. 49.1 kg/s; 24 mm.
 5. (i) 630 kPa, 275°C; 240 kPa; 201°C; 85 kPa, 126°C;
(ii) 0.638, 0.655, 0.688, 0.726, 0.739; (iii) 0.739, 0.724; (iv) 1.075.
-

CHAPTER 2

1. 6.29 m³/s.
 2. 9.15 m/s; 5.33 atm.
 4. 551 rev/min, 1:10.8; 0.885 m³/s; 17.85 MN.
 5. 4030 rev/min; 31.4 kg/s.
 6. (a) $\Omega_s = 0.501$ (rad); $D_s = 4.949$; $P = 3.658$ kW; (b) $H = 61.18$ m, $Q = 0.6402$ m³/s, $P = 468$ kW.
-

CHAPTER 3

1. 49.8°.
 2. 0.77; $C_D = 0.048$, $C_L = 2.245$.
 3. -1.3°, 9.5°, 1.11.
 4. (i) 53° and 29.5°; (ii) 0.962; (iii) 2.17 kN/m².
 5. (a) $s/l = 1.0$, $\alpha_2 = 24.8^\circ$; (b) $C_L = 0.872$.
 6. (b) 57.8°; (c) (i) 357 kPa; (ii) 0.96; (iii) 0.0218, 1.075.
 7. 141.2 kg/(sm²), 0.40, 1.30.
 8. 0.058.
 9. (a) 1.21; (c) 0.19.
-

CHAPTER 4

2. (i) 88%; (ii) 86.17%; (iii) 1170.6 K.
3. $\alpha_2 = 70^\circ$, $\beta_2 = 7.02^\circ$, $\alpha_3 = 18.4^\circ$, $\beta_3 = 50.37^\circ$.
4. 22.7 kJ/kg; 420 kPa, 117°C.
5. 91%.
6. (i) 1.503; (ii) 39.9°, 59°; (iii) 0.25; (iv) 90.5 and 81.6%.
7. (i) 488 m/s; (ii) 266.1 m/s; (iii) 0.83; (iv) 0.128.
8. (i) 215 m/s; (ii) 0.098, 2.68; (iii) 0.872; (iv) 265°C, 0.75 MPa.
9. (a) (i) 601.9 m/s; (ii) 282.8 m/s; (iii) 79.8%. (b) 89.23%.

10. (b) (i) 130.9 kJ/kg, (ii) 301.6 m/s, (iii) 707.6 K; (c) (i) 10,200 rev/min, (ii) 0.565 m, (iii) 0.845.
 11. (ii) 0.2166; (iii) 8740 rev/min. (iv) 450.7 m/s, 0.846.
 12. 1.07, 0.464.
 13. 0.908.

CHAPTER 5

1. 14 stages.
2. 30.6°C.
3. 132.5 m/s, 56.1 kg/s; 10.1 MW.
4. 86.5%; 9.28 MW.
5. 0.59, 0.415.
6. (a) 0.88; (b) 0.571.
7. 56.9°, 41°, 21.8°.
8. (i) 244.7 m/s; (ii) 25.42 kg/s, 16,866 rev/min; (iii) 38.33 kJ/kg; (iv) 84.7%; (v) 5.135 stages, 0.9743 MW; (vi) with five stages and the same loading, then the pressure ratio is 5.781; however, to maintain a pressure ratio of 6.0, the specific work must be increased to 39.37 kJ/kg; with five stages the weight and cost would be lower.
9. (a) 16.22°, 22.08°, 33.79°; (b) 467.2 Pa, 7.42 m/s.
10. (i) $\beta_1 = 70.79^\circ$, $\beta_2 = 68.24^\circ$; (ii) 83.96%; (iii) 399.3 Pa; (iv) 7.144 cm.
11. (i) 141.1 Pa, 0.588; (ii) 60.48 Pa; (iii) 70.14%.

CHAPTER 6

1. 55° and 47°.
2. 0.602, 1.38, -0.08 (i.e., implies large losses near hub).
4. 70.7 m/s.
5. Work done is constant at all radii:

$$c_{x1}^2 = \text{constant} - 2a^2[(r^2 - 1) - 2(b/a)\ln r];$$

$$c_{x2}^2 = \text{constant} - 2a^2[(r^2 - 1) - 2(b/a)\ln r];$$

$$\beta_1 = 43.2^\circ, \beta_2 = 10.4^\circ.$$

6. (i) 480 m/s; (ii) 0.818; (iii) 0.08; (iv) 3.42 MW; (v) 906.8 K, 892.2 K.
7. (i) 62°; (ii) 61.3° and 7.6°; (iii) 45.2° and 55.9°; (iv) -0.175, 0.477.
8. See Figure 6.13. For (i) at $x/r_t = 0.05$, $c_x = 113.2$ m/s.

CHAPTER 7

1. (i) 27.9 m/s; (ii) 880 rev/min, 0.604 m; (iii) 182 W; (iv) 0.0526 (rad).
2. 579 kW; 169 mm; 50.0.
3. 0.875; 5.61 kg/s.
4. 26,800 rev/min; 0.203 m, 0.525.

5. 0.735, 90.5%.
6. (i) 542.5 kW; (ii) 536 and 519 kPa; (iii) 586 and 240.8 kPa, 1.20, 176 m/s; (iv) 0.875; (v) 0.22; (vi) 28,400 rev/min.
7. (i) 29.4 dm³/s; (ii) 0.781; (iii) 77.7°; (iv) 7.82 kW.
8. (i) 14.11 m; (ii) 2.635 m; (iii) 0.7664; (iv) 17.73 m; (v) 13.8 kW; $\sigma_s = 0.722$, $\sigma_B = 0.752$.
9. (a) See text; (b) (i) 32,214 rev/min, (ii) 5.246 kg/s; (c) (i) 1.254 MW, (ii) 6.997.
10. (a) $C_p \approx 0.61$, $A_2/A_1 \approx 2.2$, $\eta_D \approx 0.769$, $2\theta \approx 11^\circ$; (b) 8.65 kPa
11. Bookwork: (i) 516 K, 172.8 kPa, 0.890; (ii) $M_2 = 0.281$, $M_2 = 0.930$,
12. (i) 0.880; (ii) 314.7 kPa; (iii) 1.414 kg/s.
13. (a) 7.358 kW; (b) 275.8 rpm, 36.7 kW.
14. (a) $\Delta W = 101.7$ J/(kg K), power = 13.07 kW; (b) $\Omega_s = 0.504$ (rad), $D_s = 5.035$.
15. $M_2 = 0.4482$, $c_2 = 140.8$ m/s.
16. (i) 465 m/s, 0.740 m; (ii) 0.546 (rad).
17. $r_{s1} = 0.164$ m, $M_1 = 0.275$.
18. (i) 372.7 m/s; (ii) 156 m/s; (iii) 0.4685; (iv) 0.046 m².

CHAPTER 8

1. 586 m/s, 73.75°.
2. (i) 205.8 kPa, 977 K; (ii) 125.4 mm, 89,200 rev/min; (iii) 1 MW.
3. (i) 90.3%; (ii) 269 mm; (iii) 0.051, 0.223.
4. 1593 K.
5. 2.159 m³/s, 500 kW.
6. (i) 10.089 kg/s, 23,356 rev/min; (ii) 9.063×10^5 , 1.879×10^6 .
7. (i) 81.82%; (ii) 890 K, 184.3 kPa; (iii) 1.206 cm; (iv) 196.3 m/s; (v) 0.492; (vi) $r_{s3} = 6.59$ m, $r_{h3} = 2.636$ cm.
9. (i) 190.3 m/s; (ii) 85.7°C.
10. $S = 0.1648$, $\eta_{ts} = 0.851$.
11. Bookwork
12. (i) 4.218; (ii) 627.6 m/s, $M_3 = 0.896$.
13. (i) $S = 0.1824$, $\beta_2 = 32.2^\circ$, $\alpha_2 = 73.9^\circ$; (ii) $U_2 = 518.3$ m/s; (iii) $T_3 = 851.4$ K; (iv) $N = 38,956$ rpm, $D_2 = 0.254$ m, $\Omega_s = 0.5685$, which corresponds (approximately) to the maximum of η_{ts} in Figure 8.15.
14. (i) 361.5 kPa; (ii) 0.8205.
15. (i) $\alpha_2 = 73.9^\circ$, $\beta_2 = 32.2^\circ$; (ii) 2.205; (iii) 486.2 m/s.
16. (i) 0.3194 m, 29.073 rpm; (ii) $\zeta_R = 0.330$, $\zeta_N = 0.0826$.

CHAPTER 9

1. (i) 224 kW; (ii) 0.2162 m³/s; (iii) 6.423.
2. (a) 2.138 m; (b) For $d = 2.2$ m, (i) 17.32 m; (ii) 59.87 m/s, 40.3 MW.
3. (i) 378.7 rev/min; (ii) 6.906 MW, 0.252 (rad); (iii) 0.783; (iv) 3.
4. Head loss in pipeline is 17.8 m. (i) 672.2 rev/min; (ii) 84.5%; (iii) 6.735 MW; (iv) 2.59%.
5. (i) 12.82 MW, 8.69 m³/s; (ii) 1.0 m; (iii) 37.6 m/s; (iv) 0.226 m.

6. (i) 663.2 rev/min; (ii) 69.55° , 59.2° ; (iii) 0.152 m and 0.169 m.
 7. (b) (i) 1.459 (rad), (ii) $107.6 \text{ m}^3/\text{s}$, (iii) 3.153 m, 15.52 m/s; (c) (i) 398.7 rev/min, $0.456 \text{ m}^2/\text{s}$; (ii) 20.6 kW (uncorrected), 19.55 kW (corrected), (iii) 4.06 (rad), (d) $H_s - H_a = -2.18 \text{ m}$.
 8. (i) 0.94; (ii) 115.2 rev/min, 5.068 m; (iii) $197.2 \text{ m}^2/\text{s}$; (iv) 0.924 m.
 9. (i) $11.4 \text{ m}^3/\text{s}$, 19.47 MW; (ii) 72.6° , 75.04° at tip; (iii) 25.73° , 59.54° at hub.
 10. (i) 6 turbines required; (ii) 0.958 m; (iii) $1.861 \text{ m}^3/\text{s}$.
 11. (a) 0.498 m; (b) 28.86 m.
 12. (i) 0.262 (rad); (ii) 0.603; (iii) $33.65 \text{ m}^3/\text{s}$.
 13. $\alpha_2 = 50.32^\circ$, $\beta_2 = 52.06^\circ$, 0.336 m, $\Omega_{sp} = 2.27$ (rad); Yes, it is consistent with stated efficiency.
 14. (a) (i) 390.9 kW, (ii) $1.733 \text{ m}^3/\text{s}$, (iii) 0.767 m and 15.06 m/s, (iv) $\alpha_2 = 65.17^\circ$ and $\beta_2 = 0.57^\circ$; (b) $\sigma = 0.298$, at $\Omega_{sp} = 0.8$, $\sigma_c = 0.1$ the turbine is well clear of cavitation (see Figure 9.21).
 15. (i) 649.5 rev/min and $0.024 \text{ m}^3/\text{s}$; (ii) 0.650 kW; (iii) 0.579 kW.
 16. (i) $110.8 \text{ m}^3/\text{s}$; (ii) 100 rpm and 3.766 m; (iii) $\alpha_2 = 49.26^\circ$ and $\beta_2 = -39.08^\circ$.
 17. At hub, $\alpha_2 = 49.92^\circ$, $\beta_2 = 28.22^\circ$; at mean radius, $\alpha_2 = 38.64^\circ$, $\beta_2 = 60.46^\circ$; at tip, $\alpha_2 = 31.07^\circ$, $\beta_2 = 70.34^\circ$.
 18. (a) 0.8495; (b) 250 rpm, $90 \text{ m}^3/\text{s}$, 22.5 MW; (c) $N_{SP} = 30.77$ rpm for model and 31.73 for prototype.

CHAPTER 10

1. $C_p = 0.303$, $\zeta = 0.51$.
 2. $\bar{a} = 0.0758$ and $\Delta p = 14.78 \text{ Pa}$.
 3. (a) $C_p = 0.35$, $\zeta = 0.59$, and $N = 12.89 \text{ rpm}$; (b) 13.13 m/s, 2.388 MW.
 4. $a = 0.145$, $a' = 0.0059$, and $C_L = 0.80$.

 neap, 346, 347
 spring, 346, 347
 Time-marching method, 208
 Tip-speed ratio, 379, 390–393
 Total-to-static efficiency, 17, 272, 294–295
 effect of reaction on, 113–115
 of stage with axial velocity at exit, 123–124, 125
 Total-to-total efficiency, 16
 of fifty percent reaction turbine stage, 121–122
 of impeller, 249–250
 of turbine stage, 105
 of zero reaction turbine stage, 123, 124
 Turbine cascade (two-dimensional), 78–92
 Ainley and Mathieson correlation, 81–83
 Dunham and Came improvements, 81
 flow exit angle, 88–91
 flow outlet angles, 81, 82
 limit load, 91–92
 optimum space to chord ratio, 85, 86
 Reynolds number correction, 83
 Soderberg's correlation, 83–85
 turbine limit load, 91–92
 turbine loss correlations, 80
 Zweifel criterion, 85–88
 Turbines
 axial-flow. *See* Axial-flow turbines
 Francis. *See* Francis turbine
 free-vortex stage, 198–200
 high speed, 38–40
 hydraulic. *See* Hydraulic turbines
 Kaplan. *See* Kaplan turbine
 off-design performance of stage, 197–198
 Pelton. *See* Pelton turbine
 radial flow gas. *See* Radial flow gas turbines
 reaction, 317
 Wells. *See* Wells turbine
 wind. *See* Wind turbine
 Turbochargers, 415
 advantages, 415
 types, 415
 Turbomachines
 categories of, 1
 as control volume, 7–8, 30
 coordinate system, 2–4
 definition of, 1–2
 efficiency, size effect on, 328–330
 flow unsteadiness, 24–25
 performance characteristics of, 32–33
 Turbomachines, axial
 blade rows in, 204

design of, 209–210
 solving through-flow problem in, 206–208
 Two-dimensional cascades. *See* Cascades,
 two-dimensional

U

Unsteadiness paradox, 25

V

Vaned diffuser, 253–254, 430–431
 Vaneless diffuser, 252–253
 space, flow in, 428–430
 Vapour pressure, 48–49
 Velocity, spouting, 271
 Velocity triangles for root, mean and tip radii,
 421, 422
 Vertical axis wind turbine (VAWT), 361
 Volute, 431
 centrifugal compressor, 220, 251–252
 centrifugal pump, 251–252
 Vorticity, secondary, 210

W

Wave power, 304. *See also* Wells turbine
 Wells turbine, 304, 334–335, 336
 blade of, velocity and force vectors acting
 on, 337
 blade solidity effect on, 340
 characteristics under steady flow
 conditions, 344
 design and performance variables, 338–341
 flow coefficient, effect on, 340

hub–tip ratio, effect on, 340
 operating principles, 335–336
 and oscillating water column, 334–335
 self pitch-controlled blades, 341, 342–346
 starting behaviour of, 341, 342
 two-dimensional flow analysis, 336–338

Whirl distribution, 190

White noise, 48

Whitfield's design of rotor, 280–283

Wind energy, availability, 357–359

Wind shear, 363–364

Wind turbine, 357, 410–411

 blade section criteria, 398–399

 control methods, 400–405

 environmental considerations, 408–411

 historical viewpoint, 359

 performance testing, 406

 power coefficient of, 367

 power output, 372–373

 Prandtl's blade tip correction for, 385–387

 rotor blade configuration, 389–396

 solidity, 379–380

 stall control, 401

 types of, 360–364

Windmills, 359

Z

Zero lift line of aerofoil, 176–177

Zero reaction turbine stage, 109–110

 Mollier diagram for, 110

 total-to-total efficiency of, 123, 124

Zweifel criterion, 85–88
